Comet 67P/Churyumov–Gerasimenko was the target of the ESA Rosetta mission. →Rosetta Spacecraft reached the comet in August 2014 and delivered on the nucleus a lander called →Philae on November 12, 2014, after a global mapping of the surface in order to choose the best landing site. The comet was discovered by Klim Ivanovich Churyumov and Svetlana Ivanovna Gerasimenko in September 1969. Its current orbital period is 6.44 years, with an aphelion at 5.68 AU and a perihelion at 1.24 AU. Observations of the nucleus with ROSETTA have revealed a stunning unexpected irregular shape with two lobes, displaying different physical, mechanical, and layering properties, signing that the comet is made of two distinct objects that came into contact. The surface of the nucleus is a heterogeneous succession of terrains with pits, depressions, boulders, or rather smooth areas. Comet 67P nucleus (Fig. 1) is about $4.1 \times 3.3 \times 1.8$ km in size for the larger lobe and $2.6 \times 2.3 \times 1.8$ km for the smaller one. Its mass is 1.0×10^{13} kg and density about 0.5 g cm^3 . It rotates in about 12.4 h. It has been inferred from the various instruments of Rosetta that the nucleus

67P/Churyumov–Gerasimenko, Fig. 1 Picture of the nucleus of comet 67P/Churyumov–Gerasimenko seen from the ROSETTA spacecraft on September 19, 2014, from a distance of about 30 km. The two lobes can be seen as well as the irregular terrains made of pits, cliffs, boulders, and rather smooth areas (Credit: ESA/Rosetta/NAVCAM)

refractory to ice ratio bulk composition could range from 3 to 6, with higher values being possible. A high uncertainty remains attached to this value. Regarding the refractory component of the nucleus, it is a mixture (roughly 50/50 in mass) of a mineral component with a high molecular weight organic material, bearing similarities with →Insoluble Organic Matter extracted from →chondritic meteorites. Dominated by water, the volatile fraction of the nucleus contains a large diversity of molecules such as CO_2 , CO , CH_3OH , and other small organic compounds among which →glycine was detected. N_2 , O_2 , as well as noble gases argon, krypton, and xenon including their major isotopes were also detected in the gaseous phase, showing they were trapped in the water ice within the nucleus and that the ice was formed and kept at a low temperature.

It has been calculated that before 1840, the comet perihelion was about 4 AU and that successive dynamical interactions with Jupiter progressively shifted it to its current position. After Rosetta mission, comet 67P reached another perihelion on November 2, 2021.

Comet 67P/Churyumov–Gerasimenko is the first cometary nucleus so closely scrutinized by a spacecraft, for such a long period of time (about 2 years), and on which an automated module has landed.

Definition

In chemistry, circular dichroism (CD) refers to the differential absorption of left- and right-handed circularly polarized light by optically active chiral molecules. Electromagnetic radiation consists of electric and magnetic fields that oscillate

perpendicular to one another and to the direction of propagation. Linearly polarized light occurs when the electric field vector oscillates only in one plane and changes in magnitude, while circularly polarized light occurs when the electric field vector rotates about its propagation direction and retains constant magnitude. It thus forms a helix propagating in space.

When circularly polarized light passes through an optically active light-absorbing medium, the velocities of its right and left polarizations differ as does the extent to which they are absorbed. CD is a measure of the difference in the amount of absorption between the two. Since circularly polarized light is “chiral,” it interacts differently with the two enantiomers of chiral molecules. Depending on the wavelength employed, CD can be used to investigate the structures of proteins, nucleic acids, small organic molecules, and charge-transfer transitions.

Circumbinary Planet

Nader Haghighipour
Institute for Astronomy, University of
Hawaii-Manoa, Honolulu, HI, USA

Definition

From dynamical point of view, three types of orbits are recognized for the motion of a planet in a binary star system. These orbits have been historically labeled as:

1. The S-type (or Satellite-type) orbit where the planet revolves around one of the stars of the binary (see ► [circumprimary planet](#))
2. The P-type (or Planetary-type) orbit where the planet revolves around the entire binary system (circumbinary orbit)

Circumbinary Planet, Fig. 1 General schematic presentation of a P-type system. The *top panel* shows the general orbital configuration of the planet and the binary stars. Both stars and the planet rotate around the center of mass of the binary (shown by CoM). However, it is customary to consider the primary star to be stationary and both the secondary and planet rotate around this star (*bottom panel*) (Figures from Haghighipour and Kaltenegger (2013))

3. The L-type (or Libration-type) where the planet moves in the same orbit as the secondary star, but 60° ahead or behind it

Figure 1 shows a circumbinary (P-type) orbit. In general, the planet and the binary revolve around their common center of mass. However, it is customary to consider the primary star to be stationary and both, the secondary and planet rotate around it.

Although observations of disks in circumbinary orbits had indicated that planets must exist in these orbital configurations, it was not until 2011 that using the data from the *Kepler* Space Telescope, a team of scientists lead by Laurant Doyle discovered the first circumbinary planet (Kepler 16b). During the following years, scientists discovered many more circumbinary planets using the *Kepler* telescope (see references below).

Definition

From a dynamical point of view, three types of orbits are recognized for the motion of a planet in a binary star system. These orbits have been historically labeled as:

1.

The S-type (or satellite-type) orbit where the planet revolves around one of the stars of the binary (see circumprimary planet)

2.

The P-type (or planetary-type) orbit where the planet revolves around the entire binary system (circumbinary orbit)

3.

The L-type (or libration-type) where the planet moves in the same orbit as the secondary star, but 60° ahead or behind it

Figure 1 shows a circumprimary (S-type) orbit. In general, the planet and the binary revolve around their common center of mass. However, it is customary to consider the primary star to be stationary, and both the secondary and planet rotate around it.

Many circumprimary planets have been discovered during the past 20 years. A complete and up-to-date list of these planets can be found at <http://www.univie.ac.at/adg/schwarz/multiple.html>.

Almost all these binary systems are wide with separations between 250 and 6000 AU. There are, however, six circumprimary systems in which the binary stars have small separations (20 AU): GL 86, γ Cephei, HD 41004, HD 196885, HD 176051, and α Centauri (note that the existence of the planet around the secondary star of this system has been challenged; see Alpha Centauri Bb). The formation of these planets in such tight binaries is one of the most outstanding questions in theoretical exoplanetary science. See the book *Planets in Binary*

Circumplanetary Disk

► Planetary Rings

Circumprimary Planet,

Fig. 1 Schematic presentation of an S-type system. The two stars of the binary (primary and secondary) revolve around their center of mass (CoM), while the planet orbits only one of the stars (*top panel*). It is, however, customary to neglect the motion of the binary around its CoM and consider the motion of the secondary around a stationary primary (*bottom panel*). Definition

Circumstellar chemistry is the group of processes able to transform the chemical nature of a cloud of gas and dust surrounding a star. This general definition encompasses both young and evolved stars out of the main sequence, the ones which may host an envelope with a non-negligible mass. Most authors, however, use the term “circumstellar chemistry” to refer to the chemical processes occurring in the ejecta of an evolved star, rather than in a cloud feeding the formation of a star or a planetary system. This entry focuses on this second more restricted definition. For a description of the chemistry in clouds around protostars and young stars see ► [hot cores](#), ► [hot corinos](#), and ► [protoplanetary disk, chemistry](#).

Overview

During their last stages, stars experience important mass loss processes, which serve to recycle the stellar material back to the interstellar medium. Massive stars ($8 M_{\odot}$) end up with a sudden and violent explosion in the form of ► [supernova](#), while low- and intermediate-mass stars ($8 M_{\odot}$) lose their mass through more gentle stellar winds, which are particularly intense during the ► [asymptotic giant branch](#) (AGB) phase. These stellar ejecta might be contaminated to a large extent by material processed through ► [stellar nucleosynthesis](#) in the interior of the star, and thus the elemental composition may be quite

different from that of the primordial cloud from which the star formed, with abundance enhancements of some elements heavier than helium, such as nitrogen and carbon (Iben and Renzini 1983; Woosley and Weaver 1986). Stellar mass loss processes give rise to circumstellar envelopes, which are sites of an extraordinary interest from a chemical point of view as they act as factories of a population of tiny dust grains and a rich variety of molecules. In fact, most circumstellar envelopes are made up of molecular gas and dust.

Stellar ejecta provide the environment where dust grains are synthesized by condensation of refractory elements and the mechanism to inject them into the interstellar medium. It is well-known that dust is a minor (about 1 % in mass) but ubiquitous component of interstellar clouds and that it is to a large extent responsible of their physical and chemical state. Dust grains, for example, provide an efficient protection against external ultraviolet radiation, and their solid surfaces can act as catalysts in the formation of molecules as important as H_2 . It is currently thought that most of the interstellar dust is in fact synthesized and supplied by the ejecta of dying stars (Gehrz 1989).

Stellar ejecta do also provide a suitable environment to synthesize and host a rich variety of molecules, some of them quite exotic by terrestrial standards. Only in IRC +10216, a prototypical circumstellar envelope around an AGB star, the molecular inventory accounts for about half of all the molecules ever discovered in space (► [molecules in space](#)). In fact, molecules make up most of the mass of envelopes around low- and intermediate-mass evolved stars and are a very important constituent of envelopes around massive evolved stars such as the red supergiant VY Canis Majoris (Ziurys et al. 2007) and yellow hypergiants (Quintana-Lacaci et al. 2007). In the case of supernova ejecta, molecules such as CO and SiO might still be present at non-negligible levels, as in the case of SN 1987A (Petuchowski et al. 1989; Liu and Dalgarno 1994), but in general the formation and survival of molecules is severely hampered by the harsh irradiation conditions to which these ejecta are subjected. Molecules in circumstellar envelopes around evolved

stars are relatively short-lived in astronomical terms (usually less than a few 10^4 years), since in their way from the star to the interstellar medium, they become completely exposed to the ultraviolet interstellar radiation field at the outer edge of the envelope, where they are ultimately photodissociated. Therefore, unlike in the case of dust, molecules are destroyed before incorporating into the interstellar medium.

Mass loss processes in evolved stars enrich the interstellar medium with metals (which in astronomical terms refer to any element heavier than helium) and dust grains and provide the main mechanism by means of which the interstellar medium is recycled with fresh material.

While matter is expelled from the stellar atmosphere and expands into outer space, it assumes a wide range of physical conditions. The number density of particles decreases by several orders of magnitude and the temperature drops from thousands of K to just 10–20 K. Along the outflow, matter is chemically processed by a wide variety of processes, such as three-body and endothermic chemical reactions in the hot surroundings of the atmosphere, condensation of dust grains a few stellar radii away from the star, and photodissociation and photoionization in the outer layers, whose resulting radicals and ions take part in exothermic and rapid neutral-neutral and ion-neutral chemical reactions. Hereafter, an overview is given on the chemical state and chemical processes at work along the various regions travelled by matter in its journey from the star to the interstellar medium (see Fig. 1).

Stellar Atmosphere and Inner Envelope

One of the most important parameters that define the chemistry of a circumstellar envelope is the elemental C/O abundance ratio at the photosphere of the central star. During the AGB phase, convective (dredge up) processes inside the star may bring out to the stellar surface an amount of carbon high enough to exceed that of oxygen (Iben and Renzini 1983). Therefore, depending on whether the elemental C/O abundance ratio at the stellar surface is lower or higher than 1, AGB stars may be either oxygen- or carbon-rich, respectively. At the temperatures and pressures of

the atmospheres of AGB stars, ► [thermochemical equilibrium](#) governs the chemical composition, which is essentially molecular but quite different depending on the elemental C/O abundance ratio. The high stability of CO makes this molecule to reach very high abundances, locking most of the limiting element and allowing for the element in excess to form, either oxygen-bearing molecules such as H_2O and SiO if $\text{C/O} < 1$, and the opposite, i.e., carbon-bearing-molecules such as C_2H_2 and HCN , if $\text{C/O} > 1$. This fact is firmly established by theoretical calculations (Tsuji 1973) and has been also extensively confirmed by observations. AGB stars have a spectral type M (effective temperature between 2000 and 3700 K), but it is interesting to note that distinct spectral signatures allow to classify them according to their elemental C/O abundance ratio into M stars (reserved for stars with $\text{C/O} < 1$), C stars (with $\text{C/O} > 1$), and S stars (with $\text{C/O} \sim 1$). The chemical composition at the stellar surface propagates to the base of the envelope and, to a large extent, to the outer layers, and it is thus of great importance for the overall chemical composition of the circumstellar envelope. In fact, observations of molecular lines arising from outer circumstellar layers (e.g., Bujarrabal et al. 1994) have confirmed the existence of circumstellar envelopes with two different types of chemical composition, which correspond to the oxygen- or carbon-rich character of the star.

The ultimate mechanism leading to the ejection of matter from a red giant star, and thus to an effective mass loss, is not completely understood, although it is very likely related to both waves induced by the pulsation of the star and radiation pressure on dust grains (Gilman 1972; Kwok 1975; Bowen 1988). This scenario, called Pulsation-Enhanced Dust-Driven Outflow (PEDDRO), is actually the most promising to explain mass loss from AGB stars (Höfner and Olofsson 2018). Mass loss processes during the AGB phase are particularly intense, with mass loss rates between 10^{-7} and $10^{-4} M_{\odot} \text{ yr}^{-1}$ and expansion velocities around $10\text{--}20 \text{ km s}^{-1}$ (Olofsson 2008). Whatever the exact mechanism of the mass loss, it occurs within a few stellar radii from the AGB star, a region which is probably the one hosting the most complex, and yet

Circumstellar Chemistry, Fig. 1 Circumstellar chemistry. Scheme of a circumstellar envelope around an AGB star. The envelope is divided into three regions: stellar atmosphere, inner envelope, and outer envelope. The top axis indicates various characteristic radii from the star: R_* is the stellar radius, r_0 indicates the end of the stellar

atmosphere, r_c is the radius of condensation of dust, and r_{PH} indicates the region where molecules start to be photo-dissociated by the ambient interstellar ultraviolet field. The bottom axes indicate the typical temperatures and number densities of particles at the various locations in the envelope

to be understood, physical and chemical processes that take place throughout the whole envelope. On the one side, the periodic pulsation of the star gives rise to shock waves which are formed between the gas infalling from the previous cycle and material pushed out by the emerging wave (Hinkle et al. 1982). On the other, a few stellar radii away from the AGB star, once the kinetic temperature has fallen below about 1000 K, those elements with a higher refractory character begin to condensate out of the gas phase in the form of tiny dust grains. The chemical composition, originally established by thermochemical equilibrium at the stellar photosphere and surroundings, is then modified a few

stellar radii away from the star due to the combined action of, at least, these two processes, i.e., shock waves and dust formation.

There are evidences of deviations from thermochemical equilibrium in the chemical composition of the inner regions of circumstellar envelopes, which come from the observation of anomalously high abundances of HCN in oxygen-rich objects (Duari and Hatchell 2000; Schöier et al. 2013), water vapor in carbon-rich envelopes (Decin et al. 2010; Neufeld et al. 2011), and ammonia (NH_3) in both oxygen- and carbon-rich envelopes (Keady and Ridgway 1993; Justannont et al. 2012). Results obtained with the Herschel

Space Observatory have widely contributed to highlight the departure from thermochemical equilibrium of inner layers of envelopes around evolved stars. Endothermic and three-body chemical reactions are effective at the high temperatures and densities of these inner layers and must play an important role in the departure from chemical equilibrium. However, the ultimate mechanism triggering this nonequilibrium is currently not well understood. Efforts have been made to model the impact of shock waves on the chemical composition of the inner envelope around an AGB star (Cherchneff 2006, 2012; Agúndez and Cernicharo 2006). It has been also suggested that the clumpy character of circumstellar envelopes may allow interstellar ultraviolet photons to penetrate into the inner regions and to induce a warm photochemistry (Decin et al. 2010; Millar 2020). Dust formation is also likely to affect the abundances of gas phase molecules in these inner regions, on the one side, because the formation of dust must occur at the expense of the gaseous material, and thus some molecules must decrease their abundances, and on the other, because chemical reactions may occur on the surface of grains resulting in an important chemical processing of the gas. An adequate theoretical description of the formation of dust is hampered by the fact that it probably occurs out of chemical equilibrium (Gail and Sedlmayr 1988). Many uncertainties exist on the interplay between the various physical and chemical processes at work in the inner regions of envelopes around AGB. In fact, this is perhaps the area of circumstellar chemistry less well understood, so that it will certainly experience significant advances in the future, in part thanks to the possibility of observing high excitation molecular lines at mm- and submm wavelengths with the unprecedented angular resolution of ► ALMA. In particular, ALMA is starting to provide a, yet not clear, picture of the processes that take place in the innermost regions around AGB stars, where dust formation occurs (Kamiński et al. 2017; Decin et al. 2017).

A further interesting aspect of the chemistry of these inner parts of circumstellar envelopes is that, due to the warm temperatures, a wide variety of refractory elements may survive in the gas phase

and participate in the formation of some exotic molecules. This is not the case of interstellar clouds, where the cold temperatures make most refractory elements to readily condense out of the gas phase. Metals (in the chemical, not astronomical, sense) such as Na, K, Al, and Ti take part in the formation of molecules such as NaCl, AlCl, KCl, AlF, NaCN, AlO, AlOH, TiO, and TiO₂ (Cernicharo and Guélin 1987; Kamiński et al. 2013). The observed abundances of these molecules are generally in good agreement with the predictions of thermochemical equilibrium calculations (Agúndez et al. 2020).

Outer Circumstellar Layers

It is well established by interferometric maps of molecular line emission that molecules in circumstellar envelopes are either concentrated around the central star or distributed in a hollow shell located far from the star. In the case of IRC +10216, for example, molecules such as HCN, CS, and SiS fall in the former category, while others such as CN, HNC, HC₃N, C₂H, and C₄H belong to the latter group (Guélin et al. 1997). These two distributions are clearly denoting two different origins for each group of molecules. Those which are concentrated around the star are formed at chemical equilibrium in the stellar atmosphere or through any of the nonequilibrium processes at work in the warm inner layers. On the other hand, those molecules which appear at a certain radial distance from the star must be originated by some process, which seems to be triggered by the penetration of ultraviolet radiation from the ambient interstellar medium. Indeed, as matter expands from the star, it is geometrically diluted (the number density of particles falls with the square of the radial distance to the star for an isotropic expansion), and molecules and dust become increasingly exposed to the external ultraviolet field. It has been argued that the appearance of a good number of molecules at about the same radial distance from the star in IRC +10216 may be related to their photodesorption from dust grain surfaces, onto which they would have been formed or deposited in advance (Guélin et al. 1993).

The most widely accepted mechanism however, which is supported by quantitative modelling

calculations by different authors, proposes that molecules distributed in the cool outer layers are formed in situ by gas phase chemical reactions, which are ultimately driven by the photodissociation, and to a lower extent photoionization, of the parent molecules injected into the expanding envelope from the inner layers (Millar et al. 2000). A circumstellar envelope around an AGB star may be, in fact, viewed as a dynamically expanding ► **photon-dominated region** (PDR). As an example to illustrate how the chemical synthesis works in this scenario, we may focus on the case of carbon-rich envelopes, where the photodissociation of the parent molecules C_2H_2 and HCN produces the radicals C_2H and CN, respectively, which in turn participate in a chain of exothermic and fast neutral-neutral reactions leading to the growth of carbon chains, such as polyynes and cyanopolyynes (Agúndez et al. 2017). A wide variety of polyynes and cyanopolyynes, and their related radicals, has been observed in carbon-rich circumstellar envelopes, noticeably in IRC +10216, a source that concentrates much of the observational and theoretical research on circumstellar chemistry (Cernicharo et al. 2000). Ion-neutral chemical reactions occur also in the outer layers of IRC +10216, but their ability to take part in the synthesis of complex molecules is limited by the relatively low ionization fraction in these regions ($\sim 10^{-7}$).

Among the families of molecules observed in circumstellar envelopes, the last incorporation has been that of molecular anions. No negatively charged molecule was known in the interstellar or circumstellar medium prior to 2006. To date, up to six different molecular anions (C_4H^- , C_6H^- , C_8H^- , CN^- , C_3N^- , and C_5N^-) have been discovered in the expanding gas of IRC +10216 (see Agúndez et al. 2010 and references therein). The formation of these molecules benefits from the extremely large rate constants of radiative association between the neutral counterparts (usually a radical with a moderately large size and a high electron affinity) and an electron (Millar et al. 2017).

It is quite remarkable to note that metals survive to an important extent in the cool outer layers of circumstellar envelopes, in spite of their high

refractory character, which tends to bring them out of the gas phase as solid condensates. Neutral and ionized atoms of Na, K, Ca, Cr, and Fe have been observed in the outer layers of IRC +10216 (Mauron and Huggins 2010) with abundances that represent a few percent of the total abundance of the element. Also, metal-containing molecules of the family of the cyanides, such as $MgNC$, $MgCN$, $HMgNC$, $AlNC$, and $FeCN$, have been observed in the outer layers of some circumstellar envelopes (see, e.g., Guélin et al. 1993). Unlike the case of NaCl and the other molecules formed at chemical equilibrium in the surroundings of the star, these molecules seem to benefit from the survival of metal atoms in the gas phase and form in situ in the cool outer layers by non-equilibrium chemical processes (Petrie 1996).

The variety and complexity of the molecules observed in carbon-rich circumstellar envelopes outstand over that observed in oxygen-rich sources. This is not very surprising taking into account the larger availability of carbon, not locked up into CO, in carbon-rich sources and the extraordinary chemical properties of this element, which can easily form carbon skeletons giving rise to a wide variety of complex molecules. The large differences in terms of variety and complexity of molecules between oxygen- and carbon-rich envelopes may be to some extent an observational bias, consequence of the overwhelming attention paid by observers to carbon-rich sources, in particular to IRC +10216. Our view on the relatively poor molecular content of oxygen-rich sources might change to some extent in the near future, thanks to the great improvement of the capabilities of radio telescopes, with particular regard to their sensitivity and spectral coverage, which allows to carry out more sensitive molecular line surveys and may extend significantly the molecular inventory of oxygen-rich envelopes (see, e.g., Ziurys et al. 2007).

Beyond the AGB Phase

The evolution of a red giant star into a white dwarf brings drastic changes on the chemical composition of the surrounding nebula. The star shrinks enormously (the stellar radius decreases from a few astronomical units down to about the radius of the

Earth), but it becomes also much hotter (the effective temperature increases from 2000–3000 K up to 8000–40,000 K) injecting an intense ultraviolet radiation field in the surrounding medium. This energetic radiation photodissociates most circumstellar molecules and ionizes the resulting atoms, leading to the formation of a ► [planetary nebula](#) (PN). The transition from the AGB to the PN phase occurs rapidly (in about 10^3 years). It is however possible to identify some objects in this transition stage, which is known as ► [protoplanetary nebula](#). The characteristics of protoplanetary nebulae are in between those of the AGB and PN phases (Kwok 1993), i.e., they still host a circumstellar envelope of gas and dust with a high molecular content, although the effects of the ultraviolet radiation field which emanates from the central star begin to be visible. For example, there is an important amount of ionized gas, and the spectra shows a series of unidentified infrared bands, which are usually assigned to polycyclic aromatic hydrocarbons (PAHs). Another important distinctive sign of protoplanetary nebulae is the appearance of fast bipolar winds (with velocities of hundreds of km s^{-1}).

The chemical processing to which circumstellar envelopes are subjected during the evolution from the AGB to the PN phase can be appreciated by comparing the molecular inventory in various well-known carbon-rich objects in different evolutionary stages, such as IRC +10216 (still in the AGB phase), CRL 2688 (a young protoplanetary nebula), CRL 618 (a protoplanetary nebula in a later stage), and NGC 7027 (a planetary nebula). The protoplanetary nebula CRL 2688, although more evolved than IRC +10216, still shares many similarities with this latter object in its chemical composition, with high abundances of unsaturated carbon chains such as C_2H , C_4H , and HC_3N . The protoplanetary nebula CRL 618 is clearly in a more advanced stage than CRL 2688, so that some important chemical differences can be appreciated, such as the relatively high abundances of the ions HCO^+ and N_2H^+ , and oxygen-bearing molecules such as H_2CO and H_2O . It is also worth to note that some abundance ratios such as HNC/HCN and $\text{HC}_3\text{N}/\text{HCN}$ increase in CRL 618, and aromatic molecules such as benzene appear. Most of these

changes are thought to be the result of the strong chemical processing driven by the ultraviolet field of the star (Cernicharo 2004). Finally, the planetary nebula NGC 7027 shows some clear chemical differences with respect to their less evolved counterparts. The circumstellar gas contains new molecules such as the cations CO^+ , CH^+ , and HCS^+ , and in general the chemical complexity, in the sense of molecules with a high number of atoms, decreases noticeably.

One of the latest findings relative to the chemistry of post-AGB objects has been the discovery of the fullerenes C_{60} , C_{70} , and C_{60}^+ in some planetary nebulae (e.g., Cami et al. 2010). Indeed, it seems that there exists a clear difference between the chemistry of circumstellar envelopes around AGB stars and post-AGB objects, with regard to the appearance of some large ring and cluster carbon-based molecules, such as benzene, PAHs, and fullerenes, in late evolutionary stages. The formation of such molecular structures in these environments is yet to be understood.

Basic Methodology

The methodology employed to study circumstellar chemistry is highly multidisciplinary, as occurs in general in molecular astrophysics. It involves astronomical observations from radio to optical wavelengths, radiative transfer models, chemical models, and laboratory experiments.

Key Research Findings

There have been several key findings that have allowed to shape our understanding of circumstellar chemistry. The radioastronomical detection of numerous molecules, some of them exotic by terrestrial standards, in the circumstellar envelope around the carbon-rich AGB star IRC +10216 was clearly one of the first key findings. This allowed to draw a picture of the different processes at work in circumstellar envelopes, such as thermochemical equilibrium, grain processes, and photochemistry (see, e.g., Lafont et al. 1982). The construction of chemical models allowed to

provide more quantitative predictions on molecular abundances (Millar et al. 2000), including the presence of molecular anions, which was later on confirmed by observations (Millar et al. 2017). The discovery of benzene in the protoplanetary nebula CRL 618 (Cernicharo et al. 2001) was also a turning point that provided evidence that the synthesis of polycyclic aromatic hydrocarbons, which are widespread in the interstellar medium, probably occurs around evolved stars. In line with this, fullerenes were later on detected in planetary nebulae (Cami et al. 2010).

Applications

The study of circumstellar chemistry is an important scientific driver of advances in other areas. For example, the observation of unidentified features in astronomical spectra motivates spectroscopic studies of new molecules in the laboratory. Also, the goal of understanding how dust is formed around evolved stars and how molecules are processed in these environments drives technological advances (e.g., Martínez et al. 2020).

Future Directions

The future will be highly shaped by recent or incoming observatories such as ALMA and JWST. ALMA has the potential to unveil the building blocks of dust in the atmospheres of AGB stars (McCarthy et al. 2019). JWST is expected to provide a significant advance in our understanding of the origin of polycyclic aromatic hydrocarbons.

Cirrus Cloud

William M. Irvine
University of Massachusetts, Amherst, MA, USA

Definition

In astronomy, cirrus clouds are sources of infrared (IR) emission detected by the ► [InfraRed Astronomy Satellite \(IRAS\)](#), a joint project of the USA,

the UK, and the Netherlands which surveyed the sky at wavelengths of 12, 25, 60, and 100 μm . The spatial distribution of this IR emission is similar in appearance to terrestrial cirrus clouds, although the latter have nothing to do with the interstellar clouds. The astronomical emission arises from interstellar dust in our galaxy, particularly that associated with the diffuse portions of interstellar clouds.

Citric Acid Cycle

Juli Peretó
Institut Cavanilles de Biodiversitat i Biologia
Evolutiva, Universitat de València, València,
Spain

Keywords

Anaplerosis · Cataplerosis · Catalytic cycle ·
Oxidative metabolism

Synonyms

[Krebs cycle](#); [Tricarboxylic acid \(TCA\) cycle](#)

Definition

Citric acid cycle is a metabolic pathway often regarded as the final step for the complete oxidation of fuel molecules. Stoichiometrically, a 2-C molecule (acetyl CoA) condenses with a 4-C molecule (oxaloacetate) to yield citrate (Fig. 1a). Two consecutive oxidative decarboxylations transform

the initial 2-C unit into two CO_2 molecules. The regeneration of oxaloacetate closes the cycle through an oxidative process. In addition to the electrons taken up by redox coenzymes (NAD(P)^+ and FAD), a part of the energy is conserved in a substrate-level phosphorylation step yielding GTP. The citric acid cycle can also be regarded as a source of biosynthetic precursors. In some organisms, the cycle operates in reverse, reductively, thus functioning as an autotrophic pathway (Fig. 1b).

History

In an elegant series of experiments on substrate oxidation in respiratory animal tissues, performed among others by Albert Szent-Györgyi (1893–1986), Carl Martius (1906–1993), and Franz Knoop (1875–1946), fragments of a sequence of the metabolic transformations were established. Those observations were completed by Hans A. Krebs (1900–1981) who proposed, in a paper coauthored by William A. Johnson, the cyclic nature of the pathway in 1937 (Krebs and Johnson 1937).

Overview

The citric acid cycle occupies a central position in the metabolic network both as a catabolic, oxidative process and as a supplier of biosynthetic precursors. The cycle is more a roundabout (or traffic circle) than a carrousel: There is a permanent flux of metabolites in and out the cycle. Some metabolites are used for biosynthetic purposes (e.g., 2-oxoglutarate as glutamate precursor or succinyl CoA for the biosynthesis of heme group or lysine, see Fig. 1a). The catalytic nature of the citric acid cycle, as well as the consumption of intermediates as biosynthetic precursors, imposes the necessity of the net synthesis and replacement of those intermediates. This process is termed anaplerosis. Anaplerotic reactions include the synthesis of oxaloacetate by pyruvate carboxylation and the synthesis of oxaloacetate or 2-oxoglutarate from aspartate or glutamate, respectively, by

Citric Acid Cycle, Fig. 1 The citric acid cycle. **(a)** Oxidative cycle. An anaplerotic reaction is shown (broken black line), as well as some biosynthetic branches starting

from cycle intermediates (in gray). The glyoxylate shunt is also shown (broken gray line). **(b)** Reductive cycle

transamination. On the other hand, the 4-C and 5-C skeletons derived from amino acid catabolism must leave the cycle to be fully oxidized (this process has been called cataplerosis (Owen et al. 2002)).

In some autotrophic microorganisms, the citric acid cycle operates in a reverse, reductive way (Fig. 1b). This pathway (also known as the Arnon-Buchanan cycle) allows the net synthesis of Acetyl CoA from CO₂. Firstly described by Daniel I. Arnon and Robert B. Buchanan in 1966 as the autotrophic carbon fixation pathway in the green sulfur bacterium *Chlorobium limicola* (Evans et al. 1966), it is also present in some proteobacteria and some members of the domain Archaea (Berg et al. 2010).

Clathrate

Henderson James Cleaves
Earth-Life Science Institute (ELSI), Tokyo
Institute of Technology, Tokyo, Japan
Blue Marble Space Institute of Science,
Washington, DC, USA
Center for Chemical Evolution, Georgia Institute
of Technology, Atlanta, GA, USA

Definition

In chemistry, a clathrate is an inclusion complex, also known as a clathrate compound, cage, or a host-guest complex, in which a molecule, aggregate of molecules, or crystal lattice of molecules (the “host”) noncovalently traps or encloses another, usually small, gas molecule (the “guest”), rendering it incapable of escaping by diffusion. The word is derived from the Latin word *clatratus*, meaning “with bars” or “a lattice.”

Especially important naturally occurring types of clathrates are ► [clathrate hydrates](#), formed from water ice and various gases such as methane, ammonia, or CO₂, and zeolite minerals.

Cross-References

► [Clathrate Hydrate](#)

Clathrate Hydrate

William M. Irvine
University of Massachusetts, Amherst, MA, USA

Definition

Clathrate hydrates are ice-like solids in which a “host” hydrogen-bonded H₂O lattice entraps a nonpolar “guest” gas molecule such as CH₄ or CO₂. It has been speculated that clathrate hydrates are important components of many outer solar system bodies including comets, the outer planets,

and their icy moons. Methane clathrate hydrates are also widely distributed in terrestrial seafloor sediments where the ambient temperature and pressure allows their existence. It is thought that their breakdown during periods of increasing temperature releases methane, a strong greenhouse gas, which may contribute significantly to global warming.

Keywords

Chemical evolution · Clay · Clay minerals ·
Montmorillonite · Phyllosilicates

Synonyms

[Argillaceous earth](#); [Clay minerals](#)

Definition

Clay is a generic term for a mineral group of complex hydrated aluminophyllosilicates that mainly form as a result of feldspar weathering and low-temperature hydrothermal alteration of many rocks.

Clays are natural, soft, earthy, fine-grained materials (less than 2 μm); they are plastic when mixed with an appropriate amount of water and hard when fired. Clays are fundamentally composed of a silicon tetrahedral layer and an aluminum octahedral layer with water trapped between the silicate sheets (Guggenheim and Martin 1995).

History

Clays and clay minerals have been mined since the Stone Age, when prehistoric man first discovered their useful properties. Clay tablets were used as the first writing medium, and clays sintered in fire were used to make the first ceramic objects. In many ancient religions and philosophies, mankind was originally created from clay; for example, in the Bible, the first man, Adam, whose name means “of the **▶ earth**,” was made from clay.

Overview

Structure

The simple crystal structure of clay consists of two basic components: a silicon tetrahedron-oxygen layer (the tetrahedral silicon can be partially replaced with Al^{3+} or Fe^{3+}) and an octahedron layer, in which an atom of aluminum, magnesium, and/or iron is surrounded by six anions (oxygen or hydroxyls). The individual units are stacked in parallel plates, one above the other, and depending upon the arrangement, different types of clay are produced. They are classified first into “layer types,” according to the

number of tetrahedral and octahedral sheets, and then into “groups,” which are differentiated by the type of isomorphic cation substitutions present. The layer types are illustrated in Fig. 1. The 1:1 (or TO) layer type consists of one tetrahedral sheet fused to an octahedral sheet and is represented by the **▶ kaolinite** group. Type 2:1 clay (or TOT) is made up of an octahedral sheet sandwiched between two tetrahedral sheets; examples include kaolinite, illite, and smectites, such as **▶ montmorillonite**. This composite unit is continuous in two directions of a plane in the c-direction (see Fig. 2) and forms packets of 2–15 elementary units (Meunier 2010). Figure 2 depicts a TOT layer-type crystal structure.

At **▶ pH** values above 2, clay particles carry a net negative charge in the space between the silica layers, referred to as the interlayer or interlamellar channel. The distance between these layers varies depending upon the layers of water or intercalated organics (Swartzen-Allen and Matijevic 1974). The negative charge can originate from several different factors, including lattice imperfections, isomorphic substitution, broken bonds, and exposed structural hydroxyl groups. The presence of a positive counterion, such as Na^+ , K^+ , or Ca^{2+} , compensates for the negative charge. The edges of

Clay, Fig. 1 Types of clays (see text)

Clay, Fig. 2 TOT layer-type crystal structure

the crystal are positively charged in at neutral and acidic pH (Swartzen-Allen and Matijevic 1974). These structural characteristics are responsible for the special properties of clays. For example, montmorillonite can take up various types of organic molecules. The molecule may be adsorbed on the clay lattice by cationic interchange, ion-dipole forces, ► [van der Waals forces](#), or hydrogen bonds.

Distribution

Clays are ubiquitous minerals on Earth; their presence can likely be traced to the early stages of the planet's formation. While various types of clays most likely formed on the continents of Earth in the Archean, the largest area of clay production would have been the ocean floor. The genesis of continental smectites can be traced back 3 or 4 billion years ago (Odin 1988).

The presence of clays in extraterrestrial environments, such as ► [meteorites](#), ► [Mars](#), and the ► [comet Tempel 1](#) (Lisse et al. 2006), helps us to understand the aqueous conditions that prevailed in the early stages of the history of the solar system, as the primary requirement for the formation of clay minerals is the presence of liquid water.

Importance

Clays are important minerals in nature and in industry. They play an integral part of terrestrial ► [biogeochemical cycles](#). These processes influence microbial ► [life](#) and the cycling of elements on planetary surfaces. Clay also plays a role in the buffering capacity of the oceans.

Clays are among the most important minerals used in the manufacturing and environmental industries; for example, the construction of ceramics, including tiles, bricks, and pottery. In addition to sand and silt, clay is one of the three principal types of sediment and primarily results from the weathering of rocks and soil on the surface of the Earth.

Importance in Chemical Evolution

Many authors have proposed that clays played a central role in ► [chemical evolution](#) and ► [origin of life](#) (Negrón-Mendoza et al. 2010; Hashizume 2012). This role is a result of the capacity of clay to adsorb organic molecules and catalyze reactions (Theng 1974; Laszlo 1987; Yariv and Cross 2002). Clay minerals are important for several purposes: (1) to concentrate the organic molecules present in a dilute ocean by adsorption on clay deposits, (2) to catalyze the polymerization of

adsorbed organic compounds, (3) to protect these organic molecules from destruction by ultraviolet light or other energy sources, and (4) as a probable mechanism to induce chirality in contemporary molecules. Investigations of the role of clays in prebiotic organic synthesis range from their capability to act as adsorbents and/or catalysts to the controversial claim that clays were the first functional templates (Cairns-Smith 1966; Cairns-Smith 1982; Cairns-Smith and Hartman 1988). Mud beds, shores, and hydrothermal vents at the bottom of the sea are all possible prebiotic scenarios in nature. In addition, these regions can be alternately wet and dry, as in tidal estuaries. These environments stress the significance of multiphase systems containing clay minerals in prebiotic processes.

An important step from chemical to biological evolution is the formation of cell membranes. Szostak and his group (2003) reported that montmorillonite accelerates the spontaneous conversion of fatty acid micelles into vesicles, which could serve as a pathway for the prebiotic encapsulation of catalytically active surfaces within membrane vesicles.

Cleanliness

J. Andy Spry
SETI Institute, Mountain View, CA, USA

Definition

For ► [planetary protection](#), the cleanliness of an environment or spacecraft hardware element is the level of contamination by something undesirable for the achievement of a space exploration goal. The maximum amount of the unwanted material is generally specified, e.g., biological cleanliness can be quantified by the number of remaining microorganisms after a cleaning process. Depending on the exploration goal, quantitation of living microorganisms, dead microorganisms, or both could be of concern. Chemical cleanliness refers to maximal specified amounts of each chemical (or group of chemicals) per unit of surface area or volume.

Cleanroom

J. Andy Spry
SETI Institute, Mountain View, CA, USA

Definition

A cleanroom is a working environment controlled to maintain the cleanliness of articles or processes taking place in that working environment. The principal control is filtration, to remove particles from the atmosphere of the cleanroom, both when air from an uncontrolled environment is flowed into the cleanroom, and when air in the cleanroom

is recycled. A continuous filtration is maintained, often with a positive pressure relative to the outside (uncontrolled) environment to maintain the particle levels at a low level. Often, other environmental parameters such as temperature and humidity will also be controlled to support particulate control.

A cleanroom standard (*ISO 14644-1*) for cleanrooms with different levels of cleanliness on a scale 1 through 8 is maintained by the International Organization for Standardization (ISO). Under previous standards (e.g., Fed209E), cleanrooms have been known by the number of particles with size under 0.5 μm /cubic foot of air (class 100,000, class 1000, class 100, etc.). Class 100,000 approximates to ISO 8, and class 1000 approximates to ISO 5, but in both standards the lower the number, the cleaner the cleanroom.

Additionally, controls are placed on personnel accessing the cleanroom and processes taking place in the cleanroom. The more stringent the cleanroom, the more controls are in place, for example: the protective garments that are worn by operators to prevent shedding of hair and skin flakes; the training needed to operate in the cleanroom; the number of operators permitted at any one time; and the types of hardware and operations that are allowed, all to limit the introduction and spread of dust and particles.

Cleanrooms are used in industry in the manufacture of articles sensitive to the presence of dust and other particulate contaminants, such as aerospace mechanisms, microelectronic devices, and precision optical devices. However, limiting the number of particles also controls the number of airborne ► [microorganisms](#) present in the cleanroom and subsequently the microbial bioburden of surfaces. For this reason, cleanrooms are also used in food manufacturing, production of sterile medical devices, and in particular the assembly of interplanetary spacecraft to support compliance with planetary protection policy.

These cleanroom standards can also be applied in smaller environments, such as cabinets, and in temporary structures, such as tents, to perform specific processes under controlled cleanliness conditions.

Climates, Diversity in the Solar System

Martin Turbet

Observatoire Astronomique de l'Université de Genève, Sauverny, Switzerland

Definition

The climate of a (solar system) planet describes the long-term average of its main meteorological components (atmospheric temperature, pressure, composition, winds, clouds, aerosols, precipitation). The climate of the terrestrial planets – with a well identified surface – is also defined by the surface meteorological components (surface temperature, precipitation, distribution of ices and liquids on the surface).

Solar system planets (and by extension, moons) have a wide diversity of climates.

Overview

The climates of the planets of the solar system can be arbitrarily separated into two distinct categories.

The first category corresponds to the telluric planets (and by extension, moons) which (1) have a clearly identified solid and/or liquid surface and (2) are endowed with a secondary atmosphere

with a high mean molecular weight. The diversity of climates of solar system terrestrial planets has been discussed in the chapter ► [“Climates, Terrestrial Planets.”](#)

The second category corresponds to the giant planets, which includes two gas giants (Jupiter and Saturn) and two ice giants (Uranus and Neptune). These four planets are characterized by a very deep (light mean molecular weight) primary atmosphere whose composition is dominated by hydrogen and helium. Giant planets do not have a clearly defined surface.

While most of the observations we have on the climates of giant planets concern the outermost layers (at pressures typically lower than 1 bar) of their atmosphere, mainly due to the presence of opaque clouds that prevent deep probing, a more complete picture can be drawn with the help of numerical atmospheric and interior models. Together observations and models taught us that the climates of solar system giant planets are characterized by (see Sánchez-Lavega et al. 2019, Fletcher et al. 2020 and references therein):

- (1) The presence of photochemical hazes, very high in the atmosphere, but much more importantly the presence of optically thick clouds, whose composition can vary between the four planets, depending on the insolation they receive (which controls atmospheric temperature) as well as their level of enrichment in heavy elements (oxygen, nitrogen, carbon, sulfur, etc.) – sometimes also known as metallicity. The clouds are made of layers of ammonia, ammonium hydrosulfide, and water on the two gas giants Jupiter and Saturn; they are mostly made of methane and hydrogen sulfide on the two ice giants Uranus and Neptune.
- (2) The existence of powerful, atmospheric jets, which move air parcels alternatively between westward (retrograde) and eastward (prograde) directions. This characteristic – common to the four solar system giant planets, and more generally to planets that have a large size and a short rotation period – produces banded appearance, with regions (or bands) of different temperatures,

composition, aerosol properties, and dynamics separated by strong meridional and vertical gradients in the zonal (east-west) winds, which can reach several hundred meters per second (Fletcher et al. 2020). The jets have been shown to reach a depth of several thousand km on Jupiter and Saturn (Kaspi et al. 2020).

- (3) The presence of (i) large scale low- and high-pressure weather systems (cyclonic and anti-cyclonic structures, respectively) and (ii) smaller scale convective storms. Many cyclonic structures and convective storms have been observed on Jupiter (e.g., the Great Red Spot, which is the largest anticyclone in the solar system; the large-scale polar cyclones seen by Juno), Saturn (e.g., the Great White Spots, which are transient convective storms), and the ice giants Neptune and Uranus (e.g., the Dark Spots seen by Voyager 2 and Hubble on Neptune). These regional transient weather phenomena are an integral part of the climate of giant planets because they can last for very long periods (e.g., the Great Red Spot of Jupiter has existed for at least several centuries) or form recurrently (e.g., the Great White Spots appear periodically each Saturnian year).

The various climatic characteristics (e.g., temperatures and winds) of giant planets can also vary with seasons, as it has now been well documented for Saturn. For instance, a seasonal change in color (from a blue to an ochre hue) of Saturn's North Pole observed by Cassini has been associated with increased photochemical haze production as the northern hemisphere summer solstice approaches.

The nature of a planet's climate is likely the most important ingredient for the habitability of a planetary surface and thus its astrobiological potential. Of the ten objects of the solar system that have an atmosphere, the Earth is the only one known to have liquid water on its surface today, an essential ingredient for life as we know it to emerge and develop. The other planets of the

solar system are, however, a great natural laboratory to better understand the functioning of the climate of the planets in the broad sense, and thus of the Earth and of the planets likely to shelter life as we know it.

Climates, Exoplanets

Martin Turbet

Observatoire Astronomique de l'Université de
Genève, Sauverny, Switzerland

Definition

The climate of an exoplanet describes the long-term average of the main meteorological components (temperature, pressure, atmospheric composition, winds, clouds, aerosols, precipitation) of the atmosphere (and possibly the surface, which in this case also includes the distribution of ices and liquids on the surface) of an exoplanet, i.e., a planet revolving around other stars than our Sun.

Overview

While the climates of solar system planets are now fairly well depicted, in particular thanks to many successful space exploration missions, our knowledge of the climates of exoplanets is still rather limited. In fact, we have only had astronomical observatories and instruments for about a decade now that allow us to probe the atmosphere and surface, and thus the climate of exoplanets.

Observations that have been made so far – by transit spectroscopy, secondary eclipse, phase curves, direct imaging or interferometry – have provided an increasing amount of information on atmospheric composition (Sing et al. 2016), thermal structure (Stevenson et al. 2014), winds (Snellen et al. 2010), clouds (Kreidberg et al. 2014), and even precipitation (Ehrenreich et al. 2020). Most of these observations are essentially restricted to large and hot exoplanets because these are the easiest exoplanets to observe and thus to study. However, the use of increasingly large telescopes and increasingly powerful instruments has made it possible in very recent years to gain information about the climates of relatively

small (Kreidberg et al. 2019) or cool (Tsiaras et al. 2019; Benneke et al. 2019) planets. Likewise, future observatories such as the James Webb Telescope or the European Extremely Large Telescope are expected to provide atmospheric and/or surface data for the first time on exoplanets that have similar characteristics (in size, mass, and insolation) to the Earth (Turbet et al. 2016; Lustig-Yaeger et al. 2019; Fauchez et al. 2019).

To fully reconstruct the climates of exoplanets for which little (for hot and large exoplanets) or no (for small and cold exoplanets) observations are available, numerical atmospheric models have proven to be very useful. These are mathematical models that equate the various physical and chemical processes in the atmosphere in order to simulate the climate of planets and exoplanets directly on a computer (Forget and Lebonnois 2013). These models are not only very useful for interpreting the available observations, but also for predicting climate components for which no observations are available. In fact, these models are the main source of information on the possible climates of exoplanets of similar size, mass, and insolation than Earth – these are also the planets with the highest astrobiological potential – for which no direct atmospheric or surface observation is available.

Observations of the atmosphere and surface of exoplanets, together with numerical atmospheric simulations, have taught us a lot about the climate(s) of exoplanets. The main lesson so far is that there is a very wide variety of possible climates on exoplanets (Forget and Leconte 2014), much greater even than in the solar system. This stems mostly from the fact that exoplanets span a much wider range of insolation, atmospheric composition, size, mass, etc., than solar system planets do.

More specifically, we have learned that the climate of the warmest, most massive planets we know of – the so-called hot Jupiters – is characterized by extreme temperatures, violent winds that can efficiently redistribute heat from the day-side to the nightside of the planet, and atmospheric composition impacted by both complex

chemistry and phase change thermodynamics (Kataria et al. 2016; Drummond et al. 2020).

We have also learned that a significant fraction of these planets (from hot Jupiters to mini-Neptunes) are covered with cloud layers that can reach very exotic compositions (Charnay et al. 2015; Parmentier et al. 2016; Sing et al. 2016) compared to what we know of planets in the solar system.

On a more speculative basis, we have begun to anticipate the possible climates of rocky and temperate planets, using atmospheric models, for various formation and evolutionary scenarios (Turbet et al. 2016, 2018; Komacek and Abbot 2019; Shields 2019). This is a major aspect of the study of the climates of exoplanets, as climate determines the ability of a planet to maintain liquid water on its surface, thus allowing life as we know it to emerge and develop.

Climates, Terrestrial Planets

Martin Turbet

Observatoire Astronomique de l'Université de Genève, Sauverny, Switzerland

Definition

The climate of a (solar system) terrestrial planet describes the long-term average of the main meteorological components (atmospheric and surface temperature, pressure, composition, winds, clouds, aerosols, precipitation, distribution of ice and liquids on the surface) of the atmosphere and surface of terrestrial planets, which includes Venus, Earth, and Mars. Mercury is excluded from the list because it has no atmosphere. However, by extension, the climate of terrestrial planets also often refers to the climate of Titan, Pluto, and Triton because these objects share two main properties: they have a surface and an atmosphere with a high mean molecular weight.

Overview

Strictly speaking, the climate of terrestrial planets refers to the climate of Venus, Earth, and Mars. But in a broader sense, it also often refers to the climate of the icy moons Titan and Triton and the dwarf planet Pluto. The main specificity of these six terrestrial bodies is that (compared to gas giants) they all have a solid and/or liquid surface and an atmosphere with a high mean molecular weight (i.e., heavier than hydrogen and helium). Their atmospheres are mainly composed of H₂O, CO₂, CH₄, SO₂, O₂, N₂, etc., which can condense and/or be photochemically altered by the photons from the Sun. This can lead to the formation of

clouds and/or hazes and subsequently to the deposition or precipitation of the molecules on the surface (in solid or liquid form), which can have a fundamental role on the state of the surface and thus by feedback on the climate.

The diversity of bulk atmospheric and surface compositions and insolation are at first order the two main factors (there are other secondary factors such as the size and mass of the object, its rotation speed, obliquity, etc.) in the richness and diversity of climates across terrestrial planets and objects in the solar system. More descriptive (but not exhaustive) elements of the climate of the six terrestrial objects mentioned above are presented below.

Venus is sufficiently irradiated ($\sim 1.9 \times$ the insolation on Earth) for all molecular species – mainly CO_2 – to be present in the gas phase. Combined with other molecular species (SO_2 , H_2O , etc.), CO_2 produces a strong greenhouse effect which warms efficiently the lower atmosphere and the surface, up to ~ 740 K. Venus' thick atmosphere (with a surface pressure $\sim 92 \times$ that of Earth) efficiently redistributes heat in the lower atmosphere, reducing temperature variations across the Venusian surface. While the middle atmosphere of Venus is characterized by the presence of a thick global layer of photochemical sulfuric acid hazes, its upper atmosphere is in a state of superrotation, i.e., with very strong zonal winds.

Earth has the right insolation and atmosphere for the water cycle (evaporation, precipitation, cloud formation) to be active and thus deeply impact Earth's climate. The Earth's atmospheric circulation (and thus cloudiness and precipitation) is dominated by large latitudinal circulation cells (Hadley, Ferrel, polar). For more than a hundred years now, humans have been emitting a significant amount of greenhouse gases (e.g., CO_2) which leads - exacerbated by the water cycle - to significant warming of the lower atmosphere and significant climate changes.

Mars is cold enough ($\sim 0.43 \times$ the insolation on Earth) for both water and CO_2 (the main atmospheric constituent) to condense on the surface, in particular at the poles. The seasonal CO_2 condensation strongly impacts the pressure, temperature

and winds in the atmosphere of Mars. Because Mars has a thin atmosphere (with a surface pressure $\sim 0.006 \times$ that of Earth) and a dry surface, the climate on Mars is hyper-continental, i.e., with extreme variations of surface temperature over the course of diurnal and seasonal cycles. Last but not least, the dust cycle has a strong effect on the Martian climate.

Titan is low enough irradiated ($\sim 0.011 \times$ the insolation on Earth) that methane and other heavier hydrocarbons (C_2H_6 , C_3H_8 , etc.; they are produced by photochemistry in the upper atmosphere) can condense in the atmosphere and at the surface, producing a hydrological cycle similar in some respects to that on Earth.

Pluto ($\sim 6.10^{-4} \times$ the insolation on Earth) is so cold that its very thin (with a surface pressure $\sim 10^{-5} \times$ that of Earth), N_2 -dominated atmosphere condenses on the surface mainly at the equator because of Pluto's high obliquity and peculiar topography. Although to date very little information is known about **Triton**, its climate is probably similar to that of Pluto.

The nature of a planet's climate is likely the most important ingredient for the habitability of a planetary surface, and thus its astrobiological potential. Of the six terrestrial objects of the solar system that have an atmosphere, the Earth is the only one known to have liquid water on its surface today, an essential ingredient for life as we know it to emerge and develop.

Definition

Clouds are condensates (either liquid or solid) of gaseous atmospheric constituents, which play an important role in planetary atmospheres. Since clouds scatter and absorb incident stellar radiation as well as emergent thermal radiation and release ► [latent heat](#) during their formation, they control both the appearance and thermal structure of a planet. Furthermore, a cloud deck can both limit the depth an external observer can “see” into an atmosphere and thus hide molecular species, and it can alter a planet’s ► [albedo](#). For such reasons, a basic understanding of the role clouds play is

required to interpret exoplanet spectra or to obtain consistent temperature profiles and surface temperatures.

Overview

Clouds can form when the partial pressure of a chemical species exceeds its saturation vapor pressure. The initial distribution of cloud nuclei is formed by either homogenous or heterogeneous nucleation from the gas phase, where the first process needs a highly supersaturated vapor phase, while the latter one already operates at very low supersaturations but requires the a priori presence of some form of seed particles (e.g., ► [aerosol particles](#)). The resulting initial distribution of nuclei undergoes numerous microphysical processes, such as growth, evaporation, coagulation, or sedimentation, which determine the temporal and spatial evolution of the cloud's particle size distribution (Pruppacher and Klett 1997). Because exoplanetary atmospheres can span a very wide range of chemical compositions as well as temperature and pressure conditions, a large number of species may form clouds.

Jupiter's atmosphere provides a point of departure for understanding the diversity of giant planet atmospheres that we expect to encounter outside of the solar system. Assuming we start at a temperature of about 2,000 K (Fig. 1), the first constituents to condense in a rising gas parcel are refractory oxides such as perovskite and corundum, followed by various magnesium silicates including enstatite and forsterite. As we move upward in the atmosphere, the temperature continues to fall and eventually water clouds form, removing H_2O from the gas phase. Above the water clouds, the atmosphere continues to cool until ammonia clouds form. It is the ammonia clouds of Jupiter, dusted by various photochemical pollutants, that we see reflecting sunlight back from the planet. In a warmer Jupiter, the atmosphere would never become saturated in water and ammonia vapor, and these species would stay in the gas phase, thus removing the bright clouds and substantially altering the appearance and color of the planet.

Direct evidence for the presence of clouds has been found in transmission spectra of several

Clouds, Fig. 1 Cloud structure expected on a Jupiter-like planet depending on its temperature (hot: bottom, cool: top). (Figure modified from Lodders (2004))

transiting extrasolar gas giants. Currently, the best example for the occurrence of high-altitude clouds is the transiting hot Jupiter HD 189733b (Sing et al. 2011). The possible existence of clouds is also debated for super-Earth planets, such as GJ 1214b (Morley et al. 2013), although better observational constraints are required to obtain more accurate estimates on the clouds' properties.

Clouds play also a crucial role for terrestrial planets. For habitable planets, the most important cloud species are water droplet and carbon dioxide and water ice clouds. Typically, the reflectivity of water clouds in the visible and near-infrared wavelength range is high in comparison to surface features. Thus, a cloudy planet is brighter and has a higher albedo than either a rocky, airless world or a planet with a deep, clear atmosphere. Cold,

high-level clouds can limit the height from which thermal flux is emitted in an atmosphere and thus hide underlying regions which might otherwise produce significant spectral features. They can also directly influence important spectral features of molecules (e.g., the potential ► [biomarker ozone](#)) originating from above the cloud layer (Vasquez et al. 2013). Clouds must be considered in any calculation of the location and extension of the ► [habitable zone](#), as they can both raise the Bond albedo, thus cooling the surface (Kasting 1991) and limit thermal emission, exhibiting a ► [greenhouse effect](#) (Kitzmann et al. 2010; Forget and Pierrehumbert 1997).

Future Directions

Clouds are intrinsically difficult to model from a priori physical considerations (see, e.g., Ackerman and Marley 2001; Helling et al. 2008; Marley et al. 2013). The detailed behavior of the terrestrial cloud cover as a function of atmospheric temperature is the leading source of uncertainty in global climate models. Predicting cloud behavior for extrasolar planets, including such issues as particle sizes, vertical distribution, and any horizontal patchiness is, therefore, difficult. Accounting for the effects of these clouds has proven challenging, and such issues must be carefully considered when spatially resolved exoplanet spectra eventually become available.

[French Space Agency](#)

Definition

The French Space Agency was established in 1961 and was tasked to implement and coordinate space policy as decided by the government, through its own teams and with national and international partners in science and industry. France is a founding member of the European Space Agency (ESA) and the Centre National d'Études Spatiales (CNES) represents the country in its council and boards. The 2368 employees working in 2020 at CNES are spread among the four main centers. The headquarters are located downtown Paris, as well as the directorate for launchers now co-located with the ESA launcher directorate. The large technical center is located in Toulouse in the south of France. Finally, CNES is also in charge of the launch base of Kourou located in French Guyana. This base is the European spaceport from which the European launchers are operated since 1973. Besides Ariane V, Vega rockets and Russian-built Soyuz rockets are launched also from there. The CNES is supporting through grants and industrial contracts most of the French activities related to space prototyping either commercial or institutional applications, supporting science in space or activities related to defense and security.

CNES was involved in manned space flight through cooperation with the Soviet Union leading to the flight of Jean-Lou Chretien in 1981 and with the United States leading to the flight of Patrick Baudry in 1985. Since then, several flights and experiments related to exobiology flew onboard the Mir space station (► [COMET](#), Exo-bio) as well as the US space shuttle. Since the international space station era, CNES is supporting manned space flight activities mainly under the auspices of ESA. Ten French astronauts flew in space. The first ones flew in the frame of bilateral agreements, later 5 of them, as, lately, Thomas Pesquet, flew under the auspices of ESA as “European astronauts with a French nationality.”

CNES is also playing a major role in the exploration of the solar system through numerous

contributions to missions sponsored by the United States, the Soviet Union then Russia, India, Japan, and China. Redundant, to be suppressed France is the first contributor to ESA mixing the mandatory and the optional programs.

CNO Cycle

Nikos Prantzos

Institut d'Astrophysique de Paris, Paris, France

Definition

The CNO cycle is a series of nuclear reactions converting H to He and using C, N, and O isotopes as catalysts; thus, the total amount of these latter species is not affected by the operation. There are three such cycles, each converting four protons to one ${}^4\text{He}$ nucleus and releasing about 6.6 MeV/nucleon or $5 \cdot 10^{18}$ erg/g. At temperatures higher than $17 \cdot 10^6$ K, encountered in stars more massive than $1.3\text{--}1.5 M_{\odot}$, depending on metallicity, rotation, etc., the CNO cycle is the dominant source of energy production, while in lower-mass stars, the proton-proton ► [\(p-p\) chains](#) dominate. Although the sum of C + N + O abundances is conserved, ${}^{12}\text{C}$ and ${}^{16}\text{O}$ are converted to ${}^{14}\text{N}$, thus ${}^{14}\text{N}$ is the main product of the CNO cycle from the chemical evolution point of view.

History

The CNO cycle is also called the Bethe-Weizsäcker cycle. Hans Bethe won the 1967 Nobel Prize in physics for his 1938 discovery of energy production in stars.

CNSA, China

William M. Irvine
Department of Astronomy, University of
Massachusetts Amherst, Amherst, MA, USA

Definition

China National Space Administration (CNSA) is the national space agency of the People's Republic of China and is responsible for the national space program and for the planning and development of space activities. China has signed governmental space cooperation agreements with Brazil, Chile, France, Germany, India, Italy, Pakistan, Russia, Ukraine, the United Kingdom, and the United States, although the 2011 Wolf Amendment by the US Congress severely limits cooperation between the CNSA and NASA. The CNSA has four launch sites within China, in Jiuquan, Taiyuan, Xichang, and Wenchang.

History

CNSA has pioneered a number of achievements in space, including becoming the first space agency to land on the far side of the Moon with Chang'e 4, bringing material back from the Moon with Chang'e 5, and being the second agency to successfully landed a rover on Mars with Tianwen-1.

CO₂ Ice Cap (Mars)

François Forget
Institut Pierre Simon Laplace, Laboratoire de
Météorologie Dynamique, UMR 8539, Université
Paris 6, Paris, France

Definition

CO₂ ice caps on ► [Mars](#) are mantles of CO₂ ice deposited above 50° latitude in both hemispheres during fall and winter. They form by condensation of CO₂ gas, the main constituent of the atmosphere, and can reach thicknesses of 50 cm to 1 m. Their surface temperature is controlled by solid-gas equilibrium with the atmosphere and ranges between 142 and 150 K. In the northern hemisphere, the CO₂ ice cap completely disappears during spring. In the southern hemisphere, the CO₂ ice does not completely sublime, leaving a perennial ► [polar caps \(Mars\)](#) 300 km across and several meters thick near the south pole.

Keywords

ASCII code · Genetic code · Programs ·
Semaphore · Turing machine

Definition

At first and most basically, a code defines a mapping between one type of information and another. For instance, the ASCII code in computer science

is the binary translation of our alphabet, mapping, for instance, the lowercase character “a” onto “1100001” and making possible for computers to store, treat, and exploit information expressed in words. “Code” is one of those terms that testify to the strong intellectual connection and mutual conceptual enrichment that, since Turing, Von Neumann, and the former systemic and cybernetic schools, has always existed between biology and computer science. Interestingly enough, the different meanings of this term in computer science is mirrored by a progressive semantic enrichment also of its use in biology.

Overview

The most celebrated biological code is without doubt the “genetic” one which maps triplets of four possible ► [nucleotides](#) (“A,” “T,” “G,” “C”) onto 1 of the 20 ► [amino acids](#) found in the ► [proteins](#) of living organisms. For instance, the triplet “AAT” is mapped onto the “Leucine” amino acid. Although the ► [genetic code](#) is not as arbitrary as the ASCII one, still a mapping table is really what defines the coding in both cases.

There is an extended, more sophisticated definition of “code” in computer science, such as when a programmer is writing a “code” to be executed by his computer. The mapping is not anymore between one type of representation and another, but pieces of the code serve as an index to executable processes, such as when a traffic light turns red requiring the driver to stop his car. An essential part of elementary instructions in computers is indeed expressed according to a specific code (like “add” or “load”), making both the central process unit and the memory participate in the execution of a whole process (such as adding numbers or copying information from one zone of the computer to another). The ambiguity recognized by many biologists in the meaning of ► [“gene”](#) can be considered in the light of these basic and extended meanings. As a matter of fact, a gene can be seen not only as coding for the associated protein but, more and more in a richer manner, as indexing a whole and sophisticated biological process that might even execute differently according to the surrounding

environment (rendering the distinction between innate and acquired characteristics much more subtle and interesting). When Richard Dawkins evolves his biomorphs (Dawkins 1996 [1986]), as described in his book “The Blind Watchmaker,” the sophistication of the obtained creatures is not so much a reflection of the genetic code used by him but rather appears as an outcome of the recursive program simply parameterized by this code. The genes boil down to a simple parameterization of a very sophisticated process responsible for the major part of the resulting complexity. A mapping is still in place, but the action/process/object mapped by the gene (such as the action/process/object mapped by a software instruction in a program) is far from static. It turns out to be a very rich one-to-many mapping, from one gene to many potential dynamical processes, the latter being capable to behave in a very sophisticated manner and very sensitively to the surrounding environment. In the most complex cases, these dynamic processes can even interfere back on the genes, requiring then to include the temporal dimension in the definition of this mapping.

Coevolution

Stéphane Tirard
Centre François Viète d'Histoire des Sciences et
des Techniques EA 1161, Faculté des Sciences et
des Techniques de Nantes, Nantes, France

History

The concept of coevolution was developed in 1964 by Paul R. Ehrlich (1932) and Peter H. Raven (1936). It consists in the evolutionary interaction between two species. Coevolution notably concerns the linked evolution in the some host-parasite relationship, each of them interacts with the evolution of the other, and the relationship stays stable.

In 1973, Leigh Van Valen (1935–2010) proposed the famous parabola of the “Red Queen’s model,” inspired by Lewis Carroll’s novel, *Through the Looking-Glass, and What Alice Found There* (1871). Alice and the Red Queen run together and they stay under the same tree all the time. The Red Queen explains to Alice: “Now, here, you see, it takes all the running you can do, to keep in the same place.” This sentence resumes the idea of coevolution in which the two species have evolved simultaneously to maintain their relationship in the same state.

Coleman-Sagan Equation

Catharine A. Conley
NASA Headquarters, Washington, DC, USA

Definition

The Coleman-Sagan equation is a method for estimating the probability of contaminating another planetary body by Earth microorganisms and was first published by S. Coleman and C. Sagan in [1965](#).

This formula can be written as $P_c = N_0 R [P_s] P_i P_R P_g$.

In planetary protection, the formulation is often used by first determining the initial number of microorganisms (N_0) that could be present on or in a spacecraft (the bioburden), and then multiplying this number by an appropriately selected set of factors representing the amount by which this number could be reduced. The first reduction in proportion (R) is dependent on parameters that would reduce the number of surviving organisms, including conditions to which the spacecraft is exposed both before and after launch. Then, while present on the spacecraft, the microorganisms have to reach the surface of the planet

(or other solar system target). The value P_i describes the probability of the spacecraft to hit the planet. This value can range from less than 1×10^{-5} for a flyby, up to one for a landing probe. The probability for a microbe to be released (P_R) in the planet's environment while the spacecraft is on the ground is generally set to one in case of crash landing. The probability of growth (P_g) in the particular extraterrestrial environment is also included in the calculation, but for targets with accessible liquid water, it is assumed to be one. The "probability of contamination" is taken to be equivalent to the fractional number of organisms that are present on a spacecraft after these various reduction factors are combined.

Settlement

Definition

Colonization is the occupation of a ► [habitat](#) or territory by a biological community or of an ecological niche by a single population of a species. Biological colonization relates to all species, from microbes – including bacteria, archaea, and ► [fungi](#) – to more complex organisms, like plants and animals. The term also applies to the occupation of new territories, including planets, by the human species. Biological colonization is a dynamic process that begins when unoccupied habitats, territories, or niches become available or when organisms acquire the ability to survive and reproduce under environmental conditions of new niches, by a process of adaptation (Fig. 1).

Overview

The colonization of new habitats involves a succession of biological communities that can be studied and, to some extent, predicted. In many cases, the biological colonization of new habitats

and territories begins with microorganisms, which has particular relevance to astrobiology. All known life forms are based on ► [carbon](#) chemistry and are related to the availability of ► [water](#). Organisms are able to colonize all environments that fall within the limits of habitability, i.e., conditions of low (Kappen et al. 1996; Cavicchioli 2006) to high temperatures (up to 122 °C, Kashefi and Lovley 2003; Takai et al. 2008), low water availability (Billi and Potts 2002; Leong et al. 2011), extreme acidity (Amaral Zettler et al. 2002; Schleper et al. 1996) or alkalinity, high pressure, salinity (Oren 2000, 2002; Pikuta and Hoover 2007), and radiation (Billi et al. 2000; Bagwell et al. 2008; Dadachova and Casadevall 2008). We find life, primarily microbial, in hot springs on the ocean floor, within the crust to depths over 3000 m (Cockell 2003), in deserts (Friedmann 1982) and on the highest mountains, in the Arctic and Antarctic ► [permafrost](#) (Rivkina et al. 2000), high in the stratosphere, in salt crystals, in acidic (up to pH 0 or negative) to very basic waters (Schleper et al. 1996; Takai et al. 2001), and in sites contaminated by nuclear radiation (Dadachova and Casadevall 2008) (Figs. 2 and 3).

The limits of metabolically active life define the habitability of celestial bodies. Biological colonization is thought to be possible wherever water could be available, such as in the permafrost of ► [Mars](#) or on ► [Europa](#) Jupiter's moon. The notion

Colonization, Biological,

Fig. 1 Cryptoendolithic (hidden within rock) microbial community colonizing sandstone, McMurdo Dry Valleys, continental Antarctica (bar 1 cm). (Copyright © 2009 Laura Zucconi (permission obtained))

of biological colonization beyond Earth leads to speculation about the transfer of life from one celestial body to another. Today, we know that the conditions suitable for the origin of life could have existed on Mars and perhaps on other planets. Many organisms are capable of surviving in a dormant state in conditions far more prohibitive than those suitable for active metabolism. Some organisms, e.g., bacteria (Horneck et al. 1994), microfungi (Onofri et al. 2008, 2012), and lichens (Sancho et al. 2007), have been shown to withstand

space vacuum, temperatures, and radiation. Thus, they are valuable model organisms for studying possible extraterrestrial life. Bacterial spores within rocks are able to withstand the shock of an [asteroid](#) impact and could therefore have been ejected from the parent planet and could also have survived the landing process. Life could thus have been transferred from one planet to another ([Lithopanspermia](#)), beginning the biological colonization of new territories (Horneck and Baumstark-Khan 2002) (Figs. 4 and 5).

Color Excess

Daniel Rouan

LESIA, Observatoire Paris-Site de Meudon, Meudon, France

Definition

The color excess is the difference between the observed ► [color index](#) of a star and the intrinsic color index predicted from its spectral type. It is a quantity that is always positive and that gives a measure of the absorption of starlight by the intervening ► [interstellar medium](#). The apparent

reddening of the starlight comes from a stronger absorption in the blue than in the red by dust particles. Generally, it's the excess of the [B-V] color index of the Johnson photometric system which is used: it is denoted E_{B-V} . The interstellar extinction, denoted A_v , is directly proportional to E_{B-V} ($A_v \approx 3 E_{B-V}$).

Column Density

Daniel Rouan
LESIA, Observatoire Paris-Site de Meudon,
Meudon, France

Definition

The column density between two points in a medium is the projected number density of a given species (H atoms, dust particles) contained in a cylinder whose length is the distance between the two points. The unit is m^{-2} . When applied to the interstellar matter lying between an object and the Earth, the hydrogen column density is proportional to the extinction, with the approximate relation: $A_v = 5 \cdot 10^{-26} N(H)$, where $N(H)$ is the column density or projected number of H atoms per square meter and A_v is the visual extinction.

Combinatorial Library

Burckhard Seelig
Department of Biochemistry, Molecular Biology
and Biophysics & BioTechnology Institute,
University of Minnesota, St. Paul, MN, USA

Definition

Combinatorial libraries are mixtures of large numbers of compounds. To study the origin and evolution of biomolecules such as nucleic acids or proteins, vast combinatorial libraries have been synthesized that contain up to 10^{15} different random RNA molecules or up to 10^{13} random polypeptides. These libraries are used in conjunction with *in vitro* selection techniques such as SELEX (systematic evolution of ligands by exponential

enrichment) or mRNA display to test the hypothesis of the emergence of functional biomolecules from random sequence space.

Synonyms

[Nucleic acid pool of random sequence](#); [Oligonucleotide library](#)

Definition

A combinatorial nucleic acid library is a large pool of DNA or RNA molecules used as the starting point of an in vitro selection or evolution experiment. Such libraries usually contain 10^{12} – 10^{16} nucleic acid molecules showing a central region – typically, 20–100 nucleotides long – of random or mutagenized sequence, flanked by two primer-binding sites of defined sequence. Since 1990, combinatorial nucleic acid libraries have been used to isolate specific nucleic acid ligands for a variety of target molecules – aptamers –, as well as nucleic acid-based catalysts for different reactions – ribozymes and deoxyribozymes–.

Definition

In chemistry, combustion is the complete or incomplete oxidation of a fuel by oxygen or other oxidants to give oxidized carbon species, such as CO (for incomplete combustion) and CO₂ (for complete combustion), water and the concomitant production of heat. For example,

Respiration is an example of a biological combustion reaction.

Keywords

Small body · Coma

Definition

A comet is a small body, formed in the outer region of the Solar System, generally in a highly eccentric orbit, and containing a large fraction of volatiles. When coming close to the Sun, ► [sublimation](#) of the ices causes the development of spectacular cometary phenomena: the coma and the dust and ion tails.

History

Comets are among the most remarkable sky phenomena for both the layman and the scientist (Fig. 1; Table 1). For a long time, their unexpected apparitions and their unknown nature induced both fascination and fear. Nowadays, they are considered as natural laboratories meeting extreme physical conditions and as key objects for understanding the history of the Solar System.

Important milestones for the science of comets were:

- The understanding that comets are not atmospheric phenomena, which was demonstrated by Tycho Brahe (1546–1601) and his colleagues who measured the parallax of the comet of 1577
- The determination of cometary orbits with the works of Isaac Newton (1644–1727) and Edmond Halley (1656–1742)
- The knowledge of the comet phenomenon, formation, and development of both the coma and the tails (end of the eighteenth and nineteenth centuries)
- The determination of the composition of comets with the emergence of spectroscopy (end of the nineteenth century) and the opening of new spectral domains (end of the twentieth century)
- The active exploration of comets with flyby and encounter space missions nowadays

Cometary science is the topic of several books and reviews (see Further Reading).

Overview

Names of Comets

The nomenclature system for comets has changed several times. The Central Bureau for Astronomical Telegrams (CBAT) and now the Minor Planet Center (MPC) of the International Astronomical Union (IAU) are in charge of attributing names to comets. A registration code is given according to the order of discovery. It consists of “C/” followed by the year of discovery, then by a letter corresponding to the half-month of the discovery, and then by an order numeral. In addition, the name of the discoverer (or of the first two discoverers) is traditionally associated. Thus, C/1995 O1 (Hale-Bopp) is the first comet discovered in the second half of July 1995, by Alan Hale and

Comet, Fig. 1 Comet C/2006 P1 (McNaught) over the Pacific. This comet became spectacular as it passed perihelion at 0.17 AU from the Sun on 12 January 2007. (© Sebastian Deiries (ESO))

(a) Official IAU designation

(b) Old-style designation before 1995

(c) Provisional designation before 1995

(d) Date of perihelion. For short-period comets, this date is chosen to be either that close to their space exploration, or that close to a near approach to Earth, or another recent one

(e) Perihelion distance [AU]

(f) Eccentricity

(g) Period (years)

(h) Remarks

Thomas Bopp. Short-period comets with a period <200 years are registered “P/” instead of “C/.” Those that have been observed at several returns are given subsequently a number: 1P/Halley, 2P/Encke, etc. See <https://www.minorplanetcenter.net/iau/lists/CometResolution.html> for more details, exceptions, and oddities.

One should be careful to comply with these IAU rules to avoid ambiguities. In particular, using only the discoverer(s) name(s), as is often the case in popular articles and even in some professional papers, should be discouraged (some discoverers were very prolific).

Cometary Orbits, Cometary Families, and Cometary Reservoirs

There are now several thousand cometary apparitions for which secure orbits could be determined. The Catalog of Cometary Orbits (Marsden and

Williams 2008) listed 3708 of them. As of April 2021, 420 comets have been observed at multiple returns and are now “numbered” short-period comets.

Some comets have slightly hyperbolic orbits, such as C/1980 E1 (Bowell). As far as this could be investigated, they just recently underwent gravitational perturbations with a planet (Jupiter in most of the cases) which changed their orbit from elliptic to hyperbolic. The apparition of a genuine interstellar comet, expelled from an extra-solar system with a high eccentricity, came only recently with 2I/Borisov discovered in September 2019. A new class, “I”, was created by the IAU for such interstellar small bodies. The first one was 1I/’Oumuamua, devoid of cometary activity.

The inspection of the Catalog of Cometary Orbits shows that there are two main families of comets:

- Short-period comets with low inclination over the ecliptic. Most of them have orbital periods close to 6 or 12 years. Their orbital evolution is governed by strong gravitational interaction with Jupiter. They are named “ecliptic comets” or “Jupiter-family comets.”
- Comets with random inclination over the ecliptic. They may have a long orbital period (“new” comets with a nearly parabolic orbit) or a short period (such as Halley’s comet). They are named “nearly isotropic comets.” To explain the continuing supply of new comets, the existence of a distant, spherical reservoir of comets was postulated (► [Oort Cloud](#)). Thus, these comets are alternatively named “Oort-cloud comets.”

Nearly isotropic comets are not believed to have formed in the Oort Cloud but in the traditional Solar System. They were subsequently ejected to the Oort Cloud following gravitational interaction with giant planets. In turn, ecliptic comets could have formed in the trans-Neptunian region, among the ► [Kuiper Belt](#). They subsequently evolved to shorter-period orbits, preserving their low inclination.

Also related to comets are Centaurs, which are intermediate objects between Kuiper-Belt objects and main-belt asteroids. Some of them, like Chiron (which is registered both as asteroid (2060) Chiron and comet 95P/Chiron), show cometary activity.

“Main-belt comets” are main-belt asteroids which occasionally show a low level of cometary activity. They are also known as “activated asteroids.” About half a dozen of such objects (e.g., 133P/Elst-Pizarro) have been recently identified. Their activity might be triggered by impacts from other small bodies (Jewitt et al. 2015; Snodgrass et al. 2017).

“Sungrazing comets” pass within a few solar radii from the Sun and are generally only detectable at that moment. More than 1900 objects have been registered as sungrazing comets from observations with space coronagraphs (SOHO or STEREO). Most of these bodies are meter-sized objects that do not survive after perihelion (Jones et al. 2018).

The Nature of Comets and Basic Cometary Processes

We now know that comet nuclei are solid icy conglomerates and that the sublimation of ices in the comet nuclei is the motor of cometary activity, following the popular model of the “dirty snowball” of Fred Whipple (1906–2004). We now realize that “snowball” is a misnomer since comet nuclei are very dark. These later are kilometer-sized low-density porous and fragile bodies (see the ► [Comet \(Nucleus\)](#) entry).

Water ice sublimates in the vacuum at temperatures greater than about 150 K. For cometary nuclei, this occurs at distances smaller than about 4 AU from the Sun; this results in the development of a cometary atmosphere: the gaseous coma. The gravity of the comet nucleus is too small to retain this atmosphere, which expands with a velocity ranging from 0.5 to a few km/s, depending on the distance to the Sun and the gas production rate. Thus, the gas density drops rapidly with increasing distance from the nucleus, and the flow becomes collision-free. The inner collisional region has a size of a few hundred to a few thousand kilometers, depending on the comet outgassing. As in laboratory molecular flows, the gas temperature drops rapidly: Temperatures in the range 10–100 K are typically observed.

The production rate of water at a distance of about 1 AU from the Sun is typically 10^{28} molecules per second (300 kg/s) for small short-period comets such as 9P/Tempel 1 and 67P/Churyumov-Gerasimenko, both the targets of space missions. It was 10^{30} molecules s^{-1} (30 t/s) for 1P/Halley and as large as 10^{31} molecules s^{-1} (300 t/s) for the giant comet C/1995 O1 (Hale-Bopp).

Comets can still be active at distances larger than 4 AU from the Sun, where water sublimation is inefficient. This situation requires the sublimation of more volatile species, such as CO, CO₂, or CH₄, that are responsible for the cometary activity. Indeed, the production of carbon monoxide was observed in ► [comet Hale-Bopp](#) at distances as far as 14 AU.

The dominant chemical process in cometary atmospheres is the progressive molecular photolysis by the solar UV radiation. The lifetime of the water molecule at 1 AU from the Sun is about 1 day, but it may be significantly shorter for complex, organic molecules. Two-body reactions are inefficient because molecules spend only a short time in the collision region where temperature is low and where the fraction of reactive ions and radicals is still low.

The primary radiation mechanisms for molecules, radicals, atoms, and ions are the ► [fluorescence](#) of their electronic and vibrational bands excited by solar radiation and thermal emission of rotational lines. Prompt (non-fluorescence) emission from radicals and atoms, following their creation in an excited state as a result of photolysis, may also occur. For rotational lines of molecules in the radio and far-infrared domains, thermal excitation by collisions with molecules, ions, and electrons is another important mechanism.

Cometary particles are dragged from the nucleus by gas. Their initial velocity is much smaller than that of the gas and depends on the particle size. The biggest “boulders” cannot escape the nucleus, which contributes to the formation of a regolith. Dust particles are repelled by the Sun, forming the sometimes spectacular dust tail, following the kinematic model first proposed by Bessel (1784–1846) and Bredichin (1831–1904). The physical process at work – the solar radiation pressure – was later explained by Svante Arrhenius (1859–1927). The biggest dust particles migrate along the cometary orbit where they form cometary trails that were first imaged by the infrared satellites IRAS and ISO. When the Earth encounters such a cometary trail, a meteor shower may be observed (the link between comets and meteor streams was first established for the case of the Perseid meteors and comet 109P/Swift-Tuttle).

Cometary ions in the coma are accelerated through magnetohydrodynamic interaction with the solar wind to velocities of several hundred km s^{-1} . They form a thin straight tail, easily distinguishable from the broad, curved dust tail. This tail is mainly composed of CO^+ and H_2O^+

ions. It is remarkable that this interaction was proposed by Ludwig Biermann (1907–1986) and modeled by Hannes Alfvén (1908–1995) before the solar wind was actually observed by space probes.

Atoms and molecules that undergo fluorescence excited by the Sun are also accelerated away from the Sun. The process is especially efficient for the resonant D lines of sodium at 589 nm. A neutral sodium tail results, which was peculiarly conspicuous in ► [comet Hale-Bopp](#) (Cremonese et al. 1997). The same process is responsible for a significant distortion of the large hydrogen coma.

Space Missions to Comets

A table listing space missions to comets is given in the ► [Comet Nucleus](#) entry. The main steps of cometary exploration were:

- The ► [VEGA](#) and ► [Giotto missions](#), which flew by 1P/Halley in March 1986, revealed the reality of a solid comet nucleus.
- The ► [Stardust mission](#), which flew through the coma of 81P/Wild 2 on 2 January 2004, sampled cometary grains and returned them to Earth for analysis on 15 January 2006.
- The ► [Deep Impact](#) mission, an active experiment, sent an impactor to the nucleus of 9P/Tempel 1 on 4 July 2005. The plume which developed after the impact was observed from the spacecraft and from the Earth. The same spacecraft, in a mission renamed EPOXI, explored 103P/Hartley 2 on 4 November 2010.
- The ► [Rosetta mission](#) (Schulz et al. 2009 and Rosetta Spacecraft entry) encountered ► [67P/Churyumov-Gerasimenko](#) in 2014–2016. An orbiter stayed in the comet vicinity for all these years, witnessing the development of cometary activity. A lander (see Philae Lander entry) reached the comet’s surface and made in situ analyses of the nucleus material.
- Comet Interceptor, an accepted mission scheduled to be launched in 2028, will place three spacecraft at the L2 Lagrange point, ready to be redirected towards target-of-opportunity new comets.

Key Research Findings

Composition of Comets: Ices and Volatiles

For a long time, the chemical study of comets was restricted to visible spectroscopy. Radicals, atoms, and ions, such as CN, CH, C₂, C₃, NH, NH₂, OH, CO⁺, etc., were observed. It was proposed in the mid-twentieth century by Karl Wurm (1899–1975) and Pol Swings (1906–1983) that these unstable species were “daughter molecules” coming from the photodestruction or photoionization by the solar UV radiation of volatile stable molecules, the “parent molecules,” released from the sublimation of nucleus ices. Proposed parents were H₂O, NH₃, CH₄, CO, CO₂, HCN, etc., that could not be directly identified by the techniques available at that time.

Confirmation came with the advent of radio, infrared, and UV spectroscopy as well as in situ mass spectroscopy. We now have a confident knowledge of the main constituents of cometary ices (Bockelée-Morvan et al. 2004; Crovisier 2004; Crovisier et al. 2004; Mumma and Charnley 2011; Cochran et al. 2015; Bockelée-Morvan and Biver 2017; Altwegg et al. 1999, 2019; Fig. 2; Table 2). The main components are water (about 80% by number), followed by carbon monoxide and dioxide. Then come methanol, ammonia, methane and other hydrocarbons (C₂H₂, C₂H₆), hydrogen sulfide, and hydrogen cyanide. Other minor constituents are identified in small amounts and can only be observed in the most productive comets. For instance, the relatively complex organic molecules formic acid (HCOOH), methyl formate (HCOOCH₃), acetaldehyde (CH₃CHO), and ethylene glycol (CH₂OHCH₂OH) were first identified by their radio lines in C/1995 O1 (Hale-Bopp). They were retrieved in comet C/2014 Q2 (Lovejoy), where glycolaldehyde (CH₂OHCHO) and ethanol (C₂H₅OH) were additionally detected (Biver and Bockelée-Morvan 2019).

Indeed, the relationship between comets and spectroscopy is exemplary and dates back from the beginning of astrophysics in the second half of the nineteenth century. Many molecular species were observed in comets before they could be studied in the laboratory.

Mass spectroscopic measurements were performed in situ on 1P/Halley with Giotto

(Altwegg et al. 1999, and references therein). However, their interpretation was hampered by the limited mass resolution and the need for detailed chemical modeling to deduce neutral abundances from the mass spectra. This problem of mass ambiguity was resolved with the equipment of the Rosetta orbiter.

The ► [Stardust mission](#) returned samples from comet 81P/Wild 2. The collecting technique which was used (cometary grains were trapped by entering an aerogel substrate with a velocity of 6 km/s) could not preserve volatiles and favored refractory material. However, a careful analysis revealed the presence of methylamine (CH₃NH₂), ethylamine (CH₃CH₂NH₂), and possibly glycine (NH₂CH₂COOH) in the returned aerogel that could be of cometary origin (Elsila et al. 2009). These species could result from the degradation of carbonaceous cometary grains rather than from the sublimation of nucleus ices.

Many features detected in cometary spectra at all wavelengths are still unidentified, suggesting that new cometary species are still to be identified. This requires further theoretical and laboratory spectroscopic studies.

The investigation of comet ► [67P/Churyumov-Gerasimenko](#) by Rosetta, especially with the ROSINA instrument, really changed our view of cometary chemistry by doubling the number of identified parent molecules (Altwegg et al. 2019). One can note the observation of highly volatile species such as N₂, O₂, and noble gases; of saturated hydrocarbons up to heptane (C₇H₁₆), and also polycyclic aromatics such as benzene (C₆H₆) and possibly naphthalene (C₁₀H₈); the detection of many complex organic molecules, confirming the presence of glycine (NH₂CH₂COOH); and the presence of a phosphorus species, possibly PO.

Comets show a large diversity in their chemical composition (Fig. 2). For instance, the CO/H₂O, CH₃OH/H₂O, or H₂CO/H₂O production rate ratios vary greatly from one comet to another, whereas the HCN/H₂O ratio is fairly constant. It is important to assess whether this diversity is correlated with different sites of formation or to different evolutions of these bodies. Indeed, from the observations of daughter species, A'Hearn et al. (1995) have identified a class of carbon-

Comet, Fig. 2 Relative production rates of cometary volatiles and their comet-to-comet variations. These rates are believed to trace the relative abundances in cometary ices. The *pink* part of each *bar* indicates the range of

variation from comet to comet. The number of comets in which the species was detected until 2017 is indicated on the *right*. (Updated from Bockelée-Morvan et al. 2004)

poor comets, for which the C₂ radical is depleted. It appears that these carbon-poor comets are mostly present among Jupiter-family comets. However, how this carbon depletion could be

related to the abundance of bona fide parent molecules is still unclear. Clues from infrared and radio spectroscopy are yet inconclusive, perhaps because the sample of investigated comets at these

wavelengths is still sparse (Crovisier et al. 2009; Mumma and Charnley 2011; A’Hearn et al. 2012; Biver and Bockelée-Morvan 2016; Dello Russo et al. 2016).

Composition of Comets: Dust and (Semi-) Refractories

Knowledge of the composition of cometary dust stems from infrared spectroscopy (with ground-based telescopes and the ISO and Spitzer space observatories) and from the samples collected in the coma of the Jupiter-family comet 81P/Wild 2 by the ► [Stardust mission](#), providing ground truth for the remote-sensing investigations

(Hanner and Zolensky 2010). Additional information comes from the analysis of interplanetary dust particles (IDPs), collected in the upper Earth’s atmosphere, which could be of cometary origin. The analysis of the material excavated in the Jupiter-family comet 9P/Tempel 1 by the ► [Deep Impact](#) experiment revealed an inner nucleus composition similar to that observed in more active Oort-cloud comets, such as 1P/Halley or C/1995 O1 (Hale-Bopp).

Cometary dust appears to be heterogeneous, with silicates in both the amorphous (glassy) and crystalline forms, Fe and Ni sulfides, and other minerals in minor amounts. The presence of carbonates and phyllosilicates is subject to debate. Cometary silicates, which constitute the most abundant part of the refractory grains, show a large diversity, comprising forsterite (Mg₂SiO₄), enstatite (MgSiO₃), olivines, and pyroxenes with a wide range in Mg/Fe. Among the 81P/Wild 2 samples were found highly refractory calcium aluminum-rich inclusions (► [CAI](#)) and fragments of ► [chondrules](#), as is usually found in primitive meteorites.

A significant fraction of cometary dust is in the form of carbonaceous grains (also known as “CHON particles”), first found in the space exploration of comet Halley. They could be a potential source of molecules, an alternative to the sublimation of volatiles from nucleus ices. They have been invoked to explain the distributed sources of H₂CO, CO, OCS, HNC, CN, etc., through photo-degradation or, more likely, thermal degradation (Cottin and Fray 2008). Polyoxymethylene (H₂CO)_n (POM), hexamethylenetetramine C₆H₁₂N₄ (HMT), HCN polymers (HCN)_n, and carbon suboxide polymers (C₃O₂)_n have been proposed as cometary analogs, and their degradation was studied in the laboratory.

► [Polycyclic aromatic hydrocarbon](#) molecules (PAHs), which are ubiquitous in the interstellar medium, are also expected to be present in comets (see the review by Li 2009 and references therein). The identification of cometary PAHs from remote sensing, using near-ultraviolet or near-infrared spectroscopy (from features near 3.4, 6, 8, and 12 μm) is subject to debate. More compelling evidence of their presence comes from mass

Comet, Table 3 The relative compositions of interstellar and cometary ices

Species	Interstellar ices in high-mass YSO ^a	Interstellar ices in low-mass YSO ^b	Cometary volatiles ^c

^aHigh-mass Young Stellar Objects such as W33A and N753S

^bLow-mass Young Stellar Objects such as Elias 16 and Elias 26 (a category to which the protosun belonged)

^cFrom Table 2 and Fig. 2

Ground-based observations, confirmed by the results from the ► [Stardust and Rosetta missions](#), have shown that cometary matter includes ices as well as crystalline and amorphous silicates, originating from the cold and hot regions of the solar nebula. This points to an important turbulent mixing of the nebula. Thus, cometary silicates differ from interstellar silicates which are rather in the amorphous state. Cometary refractory grains could have both an interstellar and a nebular origin (Wooden 2008; A'Hearn 2011).

Comets and the Origin of Life

The possible role of comets as a vector for ► [panspermia](#) was advocated in several papers, especially by Hoyle and Wickramasinghe (e.g., 1981). The objections raised to this hypothesis are the hostile radiation environment and the easy destruction of organic material following the impact on Earth.

Could liquid water exist in comets, favoring the development of life in these bodies? As was suggested by Irvine et al. (1980) and studied in detail by Podolak and Prialnik (2006), a significant pressure together with a heating source is needed for this to be possible. The latter could be provided internally by ²⁶Al radioactivity or by amorphous crystalline water ice transition. However, this would only be imaginable inside huge cometary nuclei (>100 km) or large KBOs.

The hypothesized delivery of organic molecules to the Earth by the infall of small Solar System bodies was prompted by the discovery of carbonaceous matter in meteorites in the nineteenth century. The role of comets was pointed out by Chamberlin and Chamberlin (1908) and by Oró (1961). The important content of prebiotic molecules in cometary matter, which is now confirmed, brings a renewed interest in comets for elucidating the origin of life on Earth (Despois and Cottin 2005; Thomas et al. 2006).

Basic Methodology

Comets are usually observed from ground observatories, in wavelengths ranging from UV to radio domains. Most of the detections related to the composition of the coma have been achieved from the Earth. However, since the nucleus cannot be observed when the comet is active and surrounded by its coma, space missions are the only means to observe the nucleus and study the processes that govern the formation of the coma.

Future Directions

An inescapable further step for the study of comets will be to return to Earth a sample directly

taken from a comet nucleus. The challenge is to cool the sample to preserve cometary ices. Such missions are currently under study but are not yet firmly scheduled.

Short-period comets, which have predicted returns, are presently the only practicable targets. Flybys at low velocity and rendezvous are only possible for ecliptic (Jupiter-family) comets, due to energy limitations. Up to now, the only comet not belonging to the Jupiter family that was explored was 1P/Halley; this was done with a very high flyby velocity (about 70 km/s).

Although in situ cometary explorations are invaluable, they were (and will probably be for a long time) restricted to a very small number of targets. Thus, a study of the comet diversity, which needs a statistical approach, can only be achieved with remote-sensing long-term observing programs.

COMET (Experiment)

Michel Viso

Innovaxiom, Paris, CX, France

Synonyms

[Collection en Orbite de Matériel Extra Terrestre; European Space Exposure Facility \(ESEF\)](#)

Definition

The experiment “COMET” flew actually three times on board Soviet then Russian space stations. These experiments placed in 1985 (COMET-1), 1995 (European Space Exposure Facility), and 1999 (COMET-99) (Fig. 1) outside the stations aimed to collect interplanetary dust. This material is composed of grains with a size distribution dominated by particles in the micron range. Very long collection times are required to collect some grains with a reasonable size (10 μm or more). For instance, the experiment, Orbital Debris Collection Experiment (ODCE) sponsored by [NASA](#), was flown outside the MIR space station and collected for 18 months starting in March 1996.

Alternatively, during the crossing by the Earth of meteor streams, where the fluency can be enhanced by more than one order of magnitude, short collection times can be performed. Such collections were the aim of the COMET experiments and specially for COMET-99 performed outside the MIR station during the CNES-sponsored Perseus mission. It targeted

COMET (Experiment), Fig. 1 The COMET hardware before being placed outside the MIR space station. (Photo RKA/CNES)

more specifically the collection of grains from the swarm of Leonids originated from the Tempel-Tuttle comet.

The various collectors made of ultrapure metallic foil or aerogel, a transparent silicon dioxide material of very low density ($\sim 0.06 \text{ g/cm}^3$), came back to Earth by the end of the mission. On the metallic collectors, the incident particles sublime upon impact, leaving a crater, on the rims of which remnants of the particles can be found. The aerogel collectors are designed to avoid destroying the particles while impacting the surface. Penetrating inside the aerogel, they slow down and are trapped with little alteration. The metallic collectors show a very high density of large craters, due to particles larger than $20 \mu\text{m}$ attributed to the Leonid swarm. Chemical identification was possible in one case, the EDS spectrum showing identification of Mg, Si, Ca, and Fe.

Optical scanning of the aerogel collectors locates grains as small as a few microns and reveals their penetration track. In one of the two aerogel collectors of COMET-99, two populations of grains, with a mean diameter around $5 \mu\text{m}$, have been found, with penetration tracks in two main directions. A dozen of these grains have been extracted.

The experience gained during these experiments was used preparing for the ► [Stardust mission](#).

Comet (Nucleus)

Jacques Crovisier

LESIA, Observatoire de Paris, Meudon, France

Keywords

Small body

Definition

A cometary nucleus is the small-size (typically a few kilometers in diameter) solid body in the head of a comet whose activity provides the source of the comet's appearance.

Overview

With typical sizes from about 1 km to about 50 km (as for the giant comet C/1995 O1 (Hale-Bopp)), cometary nuclei are too small to be imaged by Earth-based telescopes. This can only be done with space probes that encounter or flyby these objects at small distances. This has been possible up to now only for a restricted number of objects. These observations confirmed that cometary nuclei are really solid bodies (Fig. 1 and Table 1).

The unresolved comet nucleus can be observed when the comet is far from the Sun and inactive or when the instrumental resolution allows us to separate the nucleus emission from that of the dust coma. It is then possible to evaluate the nucleus size and to investigate its rotation, using the same methods as those used for asteroids (Lamy et al. 2004). Radar studies are also possible for the nucleus of comets coming close to the Earth (Harmon et al. 2004).

Cometary nuclei are very dark, with ► **albedos** in the range 0.02–0.06, which makes them the darkest objects of the Solar System. Rotation

Comet (Nucleus), Fig. 1 The nucleus of 9P/Tempel 1 as seen by the Deep Impact probe. The nucleus average diameter is 6 km. (© NASA/JPL-Caltech/UMD)

periods range from a few hours to a few days. Some nuclei seem to be in an excited state of rotation (e.g., they are tumbling rather than rotating around a fixed axis).

The density of comet nuclei has long been an open issue due to the difficulty to estimate the nucleus mass. Indirect evaluations were performed using the effect of nongravitational forces, caused by nucleus outgassing, on cometary orbits (Weissman et al. 2004). They all point to small densities with a large error bar, in the range 0.5–1.2 g cm^{−3}. For comet 9P/Tempel 1 an evaluation was made from the trajectories of the ejecta following the Deep Impact experiment, leading to a density of about 0.35 g cm^{−3}. A precise evaluation comes from the measurement of the trajectory perturbation of a space probe in the small gravity field of the cometary nucleus. This could be performed by Rosetta for comet 67P/Churyumov–Gerasimenko. Its bulk density is 0.54 g cm^{−3} (Pätzold et al. 2019), confirming that cometary nuclei are indeed porous bodies.

Comet nuclei are frequently observed to split, showing that they are bodies with weak tensile strength, such as rubble piles.

Comet Borrelly

Therese Encrenaz

LESIA, Observatoire de Paris – Section de Meudon, Meudon, France

Definition

Comet 19/P Borrelly is a short-period comet, discovered in 1904. Its orbital period is 6.8 years. Its semimajor axis is 3.49 AU, and the aphelion and perihelion distances to the Sun are 5.83 and 1.35 AU, respectively. Comet Borrelly was visited on September 22, 2001, by the spacecraft Deep Space 1 that approached the comet at a distance of about 2200 km. The spacecraft returned high-quality images of the comet nucleus, revealing the presence of several jets. The comet is $8 \times 4 \times 4$ km in size, and its density is estimated as 0.3 g/cm^3 . Its albedo is 0.03, a typical value for comets.

Comet Encke

Therese Encrenaz

LESIA, Observatoire de Paris – Section de Meudon, Meudon, France

Definition

► [Comet](#) 2P/Encke was named after Johannes Encke who, in 1821, calculated its orbit on the basis of previous measurements made by Pons in 1818. He predicted its return in 1821 with an accuracy of 1 day. In 1823, he identified that comet Encke had already appeared in 1786, 1795, and 1805. Comet Encke was thus the second known periodic comet. Its period (3.3 years)

is the shortest reported until today. Its perihelion is 0.33 AU. After over 60 passages since its first discovery, comet Encke appears as a weak object that has lost most of its gas and dust.

LESIA, Observatoire de Paris – Section de Meudon, Meudon, France

Definition

► [Comet](#) 21P/Giacobini-Zinner, discovered independently by Michel Giacobini in 1900 and Ernst Zinner in 1913, is a Jupiter-family comet with a period of 6.6 years; its perihelion is at 1.0 AU and its aphelion is at 6.0 AU. In September 1985, the comet was visited by the spacecraft ISEE 3, renamed International Cometary Explorer (ICE), which flew by the comet at a distance of 7,800 km. The spacecraft detected a shock front when the ionized cometary species came in contact with the solar wind. Six months before the encounter of comet Halley by five spacecraft, 21P/Giacobini-Zinner was the first comet to be investigated by a space mission.

Comet

Definition

Comet C/1995 O1 (Hale-Bopp) was discovered simultaneously by Alan Hale and Thomas Bopp on July 23, 1995, at 7.1 AU from the Sun. It was soon realized that the comet, 100 times brighter than Halley at the same heliocentric distance, was abnormally big. Its 2,400-year period brought it to perihelion on April 1, 1997, at a distance of 0.91 AU from the Sun. It was a naked-eye object for over 2 months. As all long-period ► [comets](#), comet Hale-Bopp is an ► [Oort cloud](#) comet, one of the greatest of the twentieth century. Thanks to its early discovery and its exceptional size, comet Hale-Bopp is among the few objects which have allowed a major advance in our understanding of cometary physics.

Overview

A large international observing campaign was devoted to the comet in 1996 and 1997, using ground-based and space observatories at all wavelengths, from the X-ray to the radio range. Visible cameras (in particular aboard the Hubble Space Telescope) were used to determine the coma structure and the nucleus size and rotation. ► [Parent molecules](#) were mostly studied from infrared, millimeter, and submillimeter spectroscopy, including space observations from the Earth-orbiting Infrared Space Observatory (ISO).

With a diameter of 40–80 km, the nucleus of comet Hale-Bopp is the largest cometary nucleus ever measured. Its rotation period, determined from the evolution of the jets, is 11.4 h, a typical value for cometary nuclei. In addition to the dust and plasma tails usually visible on comets, a thin sodium-atom tail, observed in the visible range, was detected for the first time (Fig. 1).

Many parent molecules were detected through infrared and millimeter spectroscopy. In addition to previously detected species (H_2O , CO, CO_2 , CH_3OH , H_2CO , HCN, H_2S , NH_3 , HNC, CH_3CN , HNC, and OCS), new molecules were found in the radio range: HCOOH , CH_3CHO , HCOOCH_3 , NH_2CHO , HC_3N , H_2CS , SO, SO_2 , and NS. The detection of HDO in the

Comet Hale–Bopp, Fig. 1 Comet Hale–Bopp, observed from Earth during its 1997 passage. (© M. Jourdain de Muizon 1997)

submillimeter range, in complement with the estimate of H_2O inferred from the radio monitoring, led to the determination of D/H. As for comets Halley and Hyakutake, the D/H was found to be 3×10^{-4} , i.e., twice its value in the terrestrial oceans; this result is important as it leads to the conclusion that only a minor fraction of water on Earth probably has a cometary origin. Ground-based observations in the near-infrared range led to the detection of H_2O , CO, CH_4 , C_2H_2 , C_2H_6 , OCS, NH_3 , as well as several radicals.

Another important result is the determination of the nature of the cometary dust, inferred from ► [Infrared Space Observatory](#) measurements. In addition to already known silicate signatures, the spectrum of Hale–Bopp, recorded over the whole infrared range, exhibited specific signatures which were attributed to forsterite, a magnesium-rich olivine (Mg_2SiO_4). This spectrum is remarkably similar to those of dust disks surrounding young or evolved stars, showing a close similarity between interstellar and cometary dust.

Comet

Definition

Known since antiquity, comet Halley is probably the most famous comet in the world. With its 76-year period, it is the only bright and out of the ecliptic plane comet whose trajectory is predictable enough for space exploration to be planned. It is also the comet that allowed the astronomer Edmund Halley to demonstrate the nature and the periodic appearance of these objects: in 1705, on the basis of previous observations, he predicted the comet's return in 1758. The comet's apparition was actually observed in December 1758, 16 years after Halley's death. The apparition of comet Halley was decisive in confirming Newton's laws of universal gravitation.

Overview

Early apparitions of comet Halley go back to antiquity. Its 1066 CE apparition was recorded in the Bayeux tapestry showing King Harold's fear shortly before the Hasting battle and the victory of William the Conqueror. In 1301, the famous Italian painter Giotto di Bondone represented the comet as the Bethlehem star in his fresco "Adoration of the Magi" in Padua.

The 1835 comet Halley apparition led to the first observations of physical phenomena such as gas and dust ejection in the form of jets and fans around the nucleus, represented, in particular, in Bessel's drawings. His "fountain model" gave the first interpretation of the motion of cometary material ejected sunward and being repelled away from the Sun. This was the first confirmation of Laplace's predictions, in 1803, about a frozen nucleus. The next apparition, 1910, was especially favorable in terms of geometrical configuration: photographs and spectra of the comet were recorded, showing emissions from several radicals and ions. At that time, secondary products (coming from the photolysis and ionization of parent molecules), observed in the visible range, were much better known than the parent molecules themselves, which are better probed at infrared and millimeter wavelengths. In 1950, based on the H and OH production rates, the astronomer Fred Whipple proposed his "dirty snowball model," which predicted that the ► [comets](#) are mainly composed of water ice together with minor amounts of dust.

The next apparition, in 1986, was not favorable in terms of geometry: with respect to the Earth, the comet was behind the Sun at the time of perihelion, on February 9, 1986. Ground-based monitoring was thus much more difficult than at the time of the 1910 apparition, and the images of the comet were much less spectacular; the best observations were performed when the geocentric distance of the comet was minimum in November 1985 and in April 1986. Despite the poor observational conditions, the development of new technologies, both for ground-based and space explorations, allowed astronomers to get an

excellent scientific return from this event. The apparition was prepared long in advance by an impressive worldwide observing campaign, including five spacecraft- and ground-based observations at all wavelengths, from the UV to the radio range, coordinated by the "International Halley Watch." The five space missions included the European Giotto mission, launched by the ESA, the two Vega missions led by the Soviet Union, and two Japanese spacecraft, Suisei and Sakigake. For the first time, images of the nucleus were obtained; in situ measurements of the cometary gas and dust were recorded; and from space and ground-based experiments, parent molecules were actually detected, thanks to the development of infrared spectrometers and millimeter heterodyne spectroscopy.

Comet Halley was recovered in October 1982, at a heliocentric distance of 11 AU, with an angular distance of only 9 arcsec from its predicted position. The observation was made at Mount Palomar Observatory (California, USA), and its recovery illustrated the growing success of ► [CCD](#) cameras in astronomy.

The Nucleus

The first images of a cometary nucleus were those of comet Halley, taken by the Vega 2 and Giotto spacecraft in 1986. They were surprising at least in two aspects: the nucleus had an elongated shape, with dimensions of $15 \times 8 \times 7$ km in size, and its mean albedo was very low (0.04). The nucleus surface was mostly covered with dark material, probably due to a carbonaceous deposit, with a surface temperature as high as 300 K; water vapor, together with dust, was outgassed through a few discrete active areas, at temperatures of about 200–220 K (Fig. 1).

The presence of carbonaceous material at the nucleus' surface was also inferred by another discovery. The mass spectrometers of the Giotto and Vega spacecraft detected unexpectedly large abundances of light elements (H, C, N, O), especially in dust particles rich under the form of complex organic compounds. This result was independently derived from the analysis of the near-infrared spectrum of Halley recorded

Comet Halley, Fig. 1 The nucleus of comet Halley, as observed by the camera of the European Giotto mission on March 13, 1986, as the spacecraft flew over the comet at a distance of 500 km. Active areas showing jets of water and dust appear on the object's left side. The dimensions of the nucleus are $15 \times 8 \times 7$ km (© ESA)

by Vega, which revealed a broad emission attributed to both saturated and unsaturated hydrocarbons. Such spectral signatures have been observed under other circumstances in interstellar spectra and also in laboratory spectra of ice mixtures irradiated by solar UV or high-energy particles.

Long-period ground-based photometric monitoring has been used to determine the rotation period of Halley's nucleus. A two-component model has been favored with a slow precession (with a period of at least 7 days) and a 2-day rotation period.

The Coma

As a first result, Whipple's "dirty snowball model" was confirmed. Water, identified by its near-infrared vibration bands, was unambiguously detected, both from the Kuiper Airborne Observatory and from the Vega IKS spectrometer. The relative water content, in number of atoms, was found to be close to 80%. In addition to water and hydrocarbons, other molecules were detected by IKS aboard Vega: CO_2 , H_2CO , and CO were

also detected in the UV range. Hydrogen cyanide HCN was detected for the first time in a comet from ground-based millimeter heterodyne spectroscopy. Some molecules are outgassed from the nucleus, but some also from the dust particles in the coma. This is the case for CO and H_2CO , which density distribution in the coma shows they are released from the dust particles, possibly from the degradation of large macromolecules and polymers (for instance, H_2CO could be released from polyoxymethylene, the polymeric form of H_2CO). Another interesting result was the reported tentative detection, by the UV spectrometer of Vega, of some polycyclic aromatic hydrocarbons (PAHs), probably naphthalene C_{10}H_8 and phenanthrene $\text{C}_{14}\text{H}_{10}$, in the close vicinity of the nucleus. Similar species have been also identified in interstellar spectra. It is in fact striking to note that all parent molecules found in comet Halley have been also detected in the interstellar medium. These results strongly suggest a link between interstellar and cometary matter.

Radio observations of the OH radical at wavelength of 18 cm were used to monitor the water production of the comet as a function of its heliocentric distance.

An important parameter measured by mass spectroscopy was the D/H ratio inferred from $\text{HDO}/\text{H}_2\text{O}$ in the coma. This ratio is diagnostic of the early conditions of the comet's formation: at low temperatures, the D/H ratio is enriched in ices due to ion-molecule and molecule-molecule reactions. D/H in comet Halley was found to be 3×10^{-4} , i.e., twice its value in the terrestrial oceans. Further observations of comets have shown that this D/H ratio in water can range from terrestrial values in some comets (e.g., comet 103P/Hartley 2) to values even higher than the one measured in comet Halley (e.g., $\text{D}/\text{H} = 5.3 \pm 0.7 \times 10^{-4}$ in comet 67P/Churyumov-Gerasimenko).

Origin and Fate of Comet Halley

As shown by its retrograde orbit, comet Halley is most likely a captured object from the Oort cloud. The [Oort cloud](#) is the reservoir to which many planetesimals were ejected by gravity

perturbations due to the ► [giant planets](#). This explains why, after so many apparitions, comet Halley is still an active body: its long period allowed it to keep a significant fraction of its icy reservoir. At each perihelion passage, the surface of comet Halley is eroded and loses about 1 m depth of ice and dust. In the future, the icy content of comet Halley will slowly decrease.

Comet Hartley 2

Therese Encrenaz
LESIA, Observatoire de Paris – Section de
Meudon, Meudon, France

Definition

Comet 103 P/Hartley 2, discovered in 1986, is a Jupiter-family comet with an orbital period of 6.46 years and a semimajor axis of 3.46 AU. Its perihelion distance to the Sun is 1.05 AU, close to Earth's orbit. In 2010, the comet approached the Earth to a distance of 0.12 AU. Radar

observations revealed an elongated shape and measured a rotation period of 18 h. On November 2010, the comet was visited by the ► [Deep Impact](#) spacecraft, renamed Epoxi, after its flyby of comet Tempel 1. Epoxi approached the comet at a distance of 700 km, measured its maximum size (2.25 km), and revealed an unexpected activity. In 2011, the Herschel space observatory measured heavy water HDO in the coma and inferred a D/H ratio close to the terrestrial value. This result suggests that the ocean water might come, at least partly, from Jupiter-family comets.

Definition

Comet Interceptor is a mission designed to characterize a long period comet (LPC), which could potentially be a dynamically new comet (DNC), or an Interstellar Object (IO). This will broaden our understanding of comet morphology, composition, and plasma environment. Most importantly, such a comet would offer a unique new viewpoint along the evolutionary path of comets from their formation to migration into the inner Solar System, as a relatively unprocessed object that will have been active for only the past few years or less, rather than a returning comet that has experienced many close approaches to the Sun.

History

The Comet Interceptor mission was selected by ESA in June 2019 as ESA's new fast-class mission in its Cosmic Vision Programme. The mission was formally adopted by ESA in June 2022.

Overview

Comet Interceptor is planned to be launched with the ESA ARIEL spacecraft in 2029 and delivered to the Sun-Earth Lagrange Point L2. It will be a

multielement spacecraft comprising a primary platform which also acts as the communications hub and two probes, one from ESA and one from JAXA, allowing multipoint observations around the target. All spacecraft will be solar powered. The spacecraft and probes will remain connected to each other at L2, where they will reside until directed to their target. The mission cruise phase will last months to years. Before the encounter, the spacecraft will detach into its separate elements, probably a few days preflyby. For very active comets, separation will be earlier, to maximize separation of the spacecraft elements, while for low activity targets, separation will occur only a few hours before the encounter takes place.

Comet Interceptor's main spacecraft and two probes will be equipped with a complementary science payload, providing different perspectives of the comet's nucleus and its gas, dust, and plasma environment. Such "multipoint" measurements will greatly improve the 3D information needed to understand the dynamic nature of a pristine comet while it is interacting with the constantly changing solar wind environment.

Previous comet missions, including ESA's pioneering spacecraft Giotto and Rosetta, encountered short-period comets. These are comets with orbital periods of less than 200 years that have approached the Sun many times along their orbits in relatively recent times and as a consequence have undergone significant changes: e.g. Rosetta's comet, 67P/Churyumov-Gerasimenko orbits the Sun once every 6.5 years while Comet 1P/Halley, visited by Giotto and other spacecraft in 1986, returns to our skies every 76 years.

Comet Interceptor is different because it will target a comet visiting the inner Solar System for the first time – perhaps from the vast Oort cloud that is thought to surround the outer reaches of the Sun's realm. As such, the comet will contain material that has not undergone much processing since the dawn of the Solar System. The mission will therefore offer a new insight into the evolution of comets as they migrate inwards from the periphery of the Solar System.

Comet Interceptor Mission, Fig. 1 Comet Interceptor has been selected as ESA's new fast-class mission. It will be the first spacecraft to visit a truly pristine comet or other

interstellar object that is only just starting its journey into the inner Solar System.

The only way to encounter dynamically new comets or interstellar objects is to discover them inbound with enough warning to direct a spacecraft to them. The time between their discovery, perihelion, and departure from the inner Solar System has until recently been very short, historically months to a year: far too little time to prepare and launch a spacecraft. This timescale is, however, lengthening rapidly, with recent advances allowing observational surveys to cover the sky more deeply, coherently, and rapidly, such as the current Pan-STARRS and ATLAS surveys, and the **Vera C. Rubin Legacy Survey of Space and Time (LSST)** under construction in Chile (www.lsst.org).]

Comet Mc Naught

Therese Encrenaz

LESIA, Observatoire de Paris – Section de Meudon, Meudon, France

Definition

Over 50 comets have been discovered by Robert H. McNaught since 1987. Comet C/2006 P1 McNaught is a special comet which crossed perihelion at 0.17 AU from the Sun in December 2006 and became, in January 2007, the brightest and largest comet observed from Earth for 40 years. Infrared observations from Earth led to the identification of a large number of parent molecules. The unusually large size of the ionized comet's tail was explored as the Ulysses spacecraft passed through it in 2007. The comet is a dynamically active ► [Oort cloud](#) comet, and its material is expected to be pristine, reflecting early conditions of the solar system's history.

Comet Shoemaker-Levy 9

Therese Encrenaz

LESIA, Observatoire de Paris – Section de Meudon, Meudon, France

Keywords

Comets

Definition

Comet Shoemaker-Levy 9 (SL9) was discovered in March 1993 by Eugene and Carolyn Shoemaker and by David Levy. At that time, it

appeared as a trail of about 20 fragments. The study of their trajectories showed that it was a Jupiter-family comet which was disrupted by tidal forces at its previous closest (perijove) passage, in July 1992. It was soon predicted that the fragments would collide with ► [Jupiter](#) at its next closest passage, in July 1994 (Fig. 1).

Overview

A collision of a comet with Jupiter is very rare: according to dynamical models, it could be expected only once every few centuries. Actually, a similar event was reported by ► [Cassini](#) at the end of the seventeenth century. As a consequence, at the time of the SL9 collision, a huge international campaign took place in order to monitor the event using all possible ground-based and space means, covering the whole spectral range, from the X-ray to the radio range. Among the spacecraft were the Galileo spacecraft (en route to Jupiter for an approach in 1995), the Hubble Space Observatory (HST), the International Ultraviolet Explorer (IUE), and the X-ray satellite ROSAT. Among the objectives were the determination of the impact altitude, the temperature rise and decay, the monitoring of the impact craters, and the search for new molecules formed by shock chemistry.

The fragments of SL9 entered the Jovian atmosphere at a latitude of 44° south (44S). Between July 16 and July 22, 1994, the impacts spread along the 44S parallel as the planet was rotating; the collisional events took place within a few minutes of the predicted impact times. As seen from Earth, the impacts took place just behind the limb and came to direct view only about 10 min later. The Galileo spacecraft, still at a distance of 1.6 AU from Jupiter, was the only observatory which could see the whole event in direct view.

The successive events were recorded with three types of data: light curves, images, and spectra. Light curves, measuring the brightness versus time at different wavelengths, allowed astronomers to determine the temperature evolution and

Comet Shoemaker-Levy 9, Fig. 1 Image of the comet Shoemaker-Levy 9 before its impact with Jupiter (© NASA)

gave an estimate of the energy budget. Images, taken from Galileo, the HST, and ground-based telescopes, recorded the meteor (cometary fragment) entry (Galileo), the ejecta trajectories (limb images from the HST), and the crater evolution (HST and ground-based telescopes). Spectra, recorded in the UV (IUE, HST), the visible, infrared, and radio range, have detected new molecular species and monitored their evolution.

Temporal Sequence of the Impacts

The collisions of each individual fragment were remarkably similar, although of different intensities, depending on the impactor size. In all cases, the light curves showed a sequence of three phases:

- The entry phase was observed as a flash by the camera and the photometer of the Galileo spacecraft.
- The explosion phase occurred 1 min later; it corresponded to the explosion of the impactor within the atmosphere and to the ascent of a fireball; HST images taken at Jupiter's limb showed ejecta up to an altitude of 3,000 km for all fragments (the smaller exploding at a higher altitude than the larger ones). The fireball increased in size adiabatically from 15 km, 10 s after the impact, to 100 km after 40 s. Explosions took place at a pressure level ranging between 0.1 and 1 bar. For the largest impacts, the temperature was over 10,000 K at the early beginning and decreased to 2,000 K after about 15 s.
- The “splash phase” was studied from the light curves, the images, and the evolution of the spectra. In particular, the monitoring of methane emissions in the near-infrared range showed a decrease of the temperature from 1,000 K at $t = 10$ min to 600 K at $t = 25$ min. HST images showed the formation of dark craters surrounded by crescent-shaped areas resulting from infalling ejecta, indicating the formation of dust, possibly including carbonaceous and silicate material (Fig. 2).

New Molecules

Several species new to Jupiter have been detected in the stratosphere during the splash phase:

- The most abundant was CO, detected both in the infrared and in the millimeter range. In particular, infrared spectra of CO showed a high excitation temperature of a few thousand K at the beginning of the splash phase.
- Water was detected in the near infrared by the (NIMS) Near Infrared Mapping Spectrometer instrument aboard Galileo and by the Kuiper Airborne Observatory, with an excitation temperature of 1,000 K.
- Sulfur species were identified by the UV spectrometer of the HST: S₂, CS₂, CS, and possibly H₂S.
- From mid-infrared spectra (10–13 μ m), NH₃, HCN, and C₂H₄ were identified.
- Ground-based millimeter heterodyne spectroscopy allowed the detection and long-term monitoring of CO, CS, OCS, and HCN.

Comet Shoemaker-Levy 9, Fig. 2 One of the first impact sites of the SL9 collision as observed by the HST. All impacts occurred at latitude 44S. The enlargement on the *left* side shows the crescent-shaped structure surrounding the main impact crater in the atmosphere (© NASA)

Comet Shoemaker-Levy 9, Table 1 New molecules formed in Jupiter atmosphere by shock chemistry

Molecule	Observations	Molecular mass in SL9 impact (g)	Elemental mass in SL9 impact	Elemental mass in a 10 ¹⁵ g fragment (comet)
H ₂ O	IR, (radio)	>2 × 10 ¹²	>1.5 × 10 ¹⁴ [O]	5 × 10 ¹⁴ [O]
CO	(IR), radio	2.5 × 10 ¹⁴		
NH ₃	(UV), IR	1 × 10 ¹³	1 × 10 ¹³ [N]	2 × 10 ¹³ [N]
HCN	IR, radio	6 × 10 ¹¹		
S ₂	UV	1.5 × 10 ¹²		
CS ₂	UV	1.5 × 10 ¹¹		
CS	(UV), radio	5 × 10 ¹¹	5 × 10 ¹² [S]	4 × 10 ¹³ [S]
H ₂ S	UV	Marginal		
OCS	Radio	3 × 10 ¹²	1 × 10 ¹⁴ [C]	2 × 10 ¹⁴ [C]
Silicate	IR	6 × 10 ¹²	8 × 10 ¹³ [Si] 4 × 10 ¹³ [Mg]	1 × 10 ¹⁴ [Si] 4 × 10 ¹³ [Mg]

The relative abundances of the newly formed species are indicated in Table 1.

Long-Term Evolution of Impact Phenomena

The new molecules formed by shock chemistry had very contrasting lifetimes. Water was the first molecule to disappear, after a few hours. Still, the water from the SL9 collision is believed to be at least partly responsible for the traces of stratospheric water discovered in 1997 by the Infrared Space Observatory and later observed by other submillimeter satellites. OCS, NH₃, and S₂ were detected during a few weeks. CO and CS₂ were observed during several months, and HCS and

CN were detectable over several years. The observed lifetimes were found to be in good overall agreement with the predictions inferred from photochemical models.

The dust observed in the impact craters could be monitored during the weeks and months following the collision. The clouds first extended in longitude as an effect of Jupiter’s fast rotation and, after a couple of weeks, formed a continuous band at latitude 44S. During about a year, the clouds extended in latitude between 20S and 80S. Aerosols, first formed in the stratosphere, moved downward, contributing to the atmospheric profile cooling, to reach tropospheric levels after about a year.

Magnetospheric Effects

The Jovian ► [magnetosphere](#) was also affected by the collision. The synchrotron radiation, monitored at centimeter wavelengths, showed an enhancement of a few tens of percent during the week of impacts. The emission was mostly observed at localized longitudes, between 100 and 240°, showing evidence for a new population of excited electrons. This region correlates with the side where the magnetic field lines cross the radiation belts, intercepting the disk of Jupiter around latitude 44S.

Auroral phenomena were also recorded, in some cases, prior to the impacts, implying a strong heating of the upper stratosphere, in particular UV emissions of H and H₂, and H₃⁺ in the infrared. Often, auroral emissions were detected at the location of the northern counterparts of the impact sites, corresponding to the footprints of the connecting magnetic field lines: X-ray emissions were recorded by the ROSAT satellite at the time of two impacts; UV emissions were observed by the HST; and H₃⁺ near-IR emissions were detected from the terrestrial ground-based facilities.

About the SL9 Comet

All astrometric measurements performed before and during the collision were used to retrieve the best orbital fits ever obtained for a comet. The progenitor of comet SL9 had been captured by Jupiter nearly in the year 1930. Before its capture, the comet's orbit was probably within Jupiter's orbit, with a low eccentricity and a low inclination.

From the disruption of the comet's nucleus in 1992, its tensile strength was inferred. The very low value, 100 Pa, is consistent with a fluffy aggregate of submicron particles. Models of the swarm elongation are consistent with a progenitor of 1.5 km in size, with a density of 0.5 g/cm³. These numbers are consistent with the estimates inferred for the impactors on the basis of the impact dynamical models. The comet's activity was measured in 1993 and 1994 before the impact. Very low dust production rates were estimated (1–5 kg/s for the different impacts). No gaseous activity was

detected; an upper limit of 10²⁷ mol/s was retrieved for the OH production rate.

Information about the comet's composition was obtained from visible spectra taken during some impacts that showed a variety of atomic lines (Fe, K, Ca, H, Na, Mg, Mn, Cr, and for the first time, Li). UV spectra taken by the HST also showed atomic and ionic transitions: H, He, S, Si, Mg⁺, Fe⁺, Si⁺, and Al⁺. All these species, absent from Jupiter's spectrum, belong to the impactor; they are frequently observed in the spectra of sun-grazing ► [comets](#).

The composition of SL9 is difficult to retrieve from the new molecules formed during the impacts because they result from a recombination of products partly possibly having a planetary origin. Still, the oxygen and sulfur-bearing molecules, absent from Jupiter's stratosphere, can be used to infer the O and S content of the impactor. The inferred O/S is consistent with cometary values. The carbon content of the impactor cannot be inferred as the new molecules may have been formed from Jovian methane. Assuming that all the nitrogen of the new molecules is coming from the impactor, the inferred N/O ratio is consistent with a cometary origin. The Si/O ratio inferred from the silicate signature at 10 μm is also in agreement with typical cometary values. In conclusion, several facts support a cometary rather than asteroidal origin for the impactor: the small size, the weak but real level of activity, the low density, the very low tensile strength, the chemical composition, and the presence of silicates. Comet SL9 was actually a very small and very common Jupiter-family comet.

In summary, the collision of comet SL9 with Jupiter has not allowed astronomers to fully understand the nature and the composition of the comet; however, it provided a real-time observation of the response of a planetary atmosphere to a large meteoritic impact.

LESIA, Observatoire de Paris – Section de
Meudon, Meudon, France

Definition

► [Comet](#) 81 P/Wild, also named Wild 2, was discovered in 1978. After a passage close to Jupiter in 1974, its orbit moved toward the inner solar system, with a high ellipticity and a short period (6.4 years). Its perihelion is close to 1 AU. In January 2004, comet Wild 2 was approached by the Stardust spacecraft which collected cometary grains from its tail and brought them back to Earth in 2006. This cometary matter included material originating from different regions of the solar system before being incorporated into the comet nucleus. The presence of glycine, the simplest amino acid, has been reported in the cometary

samples. Comet Wild 2 is the only comet for which samples have been brought back to Earth and analyzed.

History

Since ancient times, ► [comets](#) have raised questions and polemics. Visual observations of comets date back to the eleventh century BCE, when Chinese chronicles related a cometary apparition to war between two kings. There are many references in classical literature, including Pliny's report of a comet during the Battle of Salamis (480 BCE). During the Middle Ages in Europe, comets were seen as portents, of the Norman conquest of England in 1066 in the Bayeux Tapestry and of the birth of Jesus as depicted by Giotto in 1304. The New World also linked comets and important events, including that observed by the Aztec emperor Moctezuma, prior to the conquest of Mexico by Cortes. If the Chaldean considered them as planets, some Greek philosophers such as Aristotle situated them in the area between the Earth and the Moon. From the sixteenth century, comets were being studied more systematically. Their movements were described through the constellations; an interest is taken in their tail's orientation with regard to the Sun, and an estimation of their parallax puts them definitely beyond the Moon (the turning point in

the study of comets was made with Tycho Brahe's observations of the parallax of the comet of 1577).

It is since the universal gravitation law, proposed by Newton in 1687 in his *Philosophiae Naturalis Principia Mathematica*, that the astronomer Edmund Halley identified the 1682 comet with those of 1607 and 1531 and predicted its return for 1759: at this moment, it was proved that those celestial bodies were bound, like planets, by gravitation, describing on the other hand elliptical (in that case they are periodical), parabolic, or hyperbolic orbits about the Sun. Then, in the nineteenth century, attention turned to the origin and the composition of those heavenly bodies. Analysis of the spectrum and polarization of light permitted astronomers at this time to identify in the comet's coma (atmosphere; from the Latin word for "hair") and tail both dust and atoms and small molecules (typically photodissociation products). It is only in 1950 that the American astronomer Fred Whipple described the comets as "dirty snowballs," speculating that their nucleus is essentially constituted of watered ice mixed with carbonic ice, silicates, and organic compounds. It is also in 1950 that Dutch astronomer Jan Oort calculated that long-period comets came from a gigantic spherical reservoir, containing thousands of millions of those little bodies, and located them at 1 or 2 light years from the Sun. Starting with the return of Comet Halley in 1986, radio and infrared astronomers have identified many molecular constituents of comets by observing their emission at millimeter wavelengths. In 2006, the Stardust space probe brought back to Earth dust from the Wild-2 comet, out of which analysis led to new knowledge on the solar system.

Commercial Use of Space

Klara Anna Capova

Department of Anthropology, Durham University, Durham, UK

Synonyms

[Privatization of space](#); [Space tourism](#)

Acronyms

EU	European Union
OECD	Organisation for Economic Co-operation and Development

Overview

The Space Economy is defined by the OECD as the full range of activities and the use of resources that create value and benefits for human beings in the course of exploring, researching, understanding, managing, and utilizing space. The commercial use of space involves currently mostly satellite technologies (navigation, communication), with the prospect of new fields such as recovery of space resources (space mining), space tourism, and other private undertakings.

In 2015, the US Commercial Space Launch Competitiveness Act was signed, encouraging commercial exploration and resource utilization

activities. In 2020, the European Council adopted a set of conclusions related to the key principles for the global space economy. The Council noted the emergence of a highly competitive European space industry and supply chains, which enabled Europe to participate in (and contribute to) the global growth of the space economy. The 2021 Space Economy Report estimated that the consolidated space economy, including both government space investments and commercial space, valued at \$385 billion in 2020, with commercial space revenues totaling over \$310 billion.

With the anticipated growth of the space economy that also includes commercial activities such as private spaceflight (also referred to as space tourism), a number of implications for scientific pursuit have emerged. Of importance to astrobiology is the potential future privatization and commodification of space resources and commercial exploration of celestial bodies. While sites of special scientific, astrobiological, or cultural significance (e.g., rover landing sites on Mars, first-landing sites on the Moon) may need comprehensive protection from commercial use, other locations may also be candidates for both scientific examination and commercial activity. This may lead to potential conflicts of interest between conduct of science and commercial use of space.

The questions of whether astronomical objects are regarded to be exploitable natural resources (Olson 2012) or whether celestial bodies can even be owned (Milligan 2014) are being discussed. Protocols for site evaluation may need to be developed, together with a code of conduct of commercial activities as related to space science, and multilateral agreements for sustainable use of space.

Synonyms

[Concestor](#); [Most recent common ancestor](#); [MRCA](#)

Definition

A common ancestor is the ancestral biological entity from which a group of other biological entities have evolved. Examples of biological entities are species, biological structures, or molecular [▶ sequences](#). One of the main ideas of Charles Darwin in *The Origin of Species* (1872) is that species are related by common ancestry, i.e., that species have evolved by divergence from a common ancestral specie. As a result of evolution by divergence from a common ancestor, the phylogenetic relationships among species or other biological entities can be described using a treelike structure. The related concept of most recent common ancestor (MRCA) specifies the least ancient common ancestor.

Compatible Solute

Josefa Anton
Department of Physiology, Genetics and
Microbiology, University of Alicante, Alicante,
Spain

Keywords

Haloadaptation · Halophile · Halotolerant

Definition

A compatible solute is a substance compatible with the cellular metabolism that accumulates in the cytoplasm to balance external osmotic pressure. This accumulation can be due to either transport from the medium or de novo synthesis and helps maintain turgor pressure, cell volume, and concentration of electrolytes, all needed for cell viability and proliferation.

Overview

Microorganisms cope with osmotic stress (due to high salt, freezing, and/or desiccation) by using

Word range of Entry: approx. 1200 words excl. references, as agreed with the Editors-in-Chief

two different types of strategies. *Archaea* of the order *Halobacteriales*, anaerobic *Bacteria* belonging to the order *Haloanaerobiales*, and some members of the *Bacteroidetes* (i.e., *Salinibacter ruber*) accumulate high concentrations of inorganic ions (mostly potassium) in the cytoplasm. This is known as the “salt-in” strategy and requires the adaptation of the entire intracellular machinery in order to function in this highly saline environment. The second strategy relies on intracellular accumulation, either by uptake or de novo synthesis, of low-molecular-weight organic-compatible solutes (also called osmolytes) to balance the external osmotic pressure. The accumulation of such solutes is very widespread in nature since the cytoplasm of most organisms does not tolerate salt. In addition, this is a very versatile strategy that allows for rapid response to changing environments since organisms can regulate their intracellular concentration according to the surrounding salinity.

Compatible solutes are small organic molecules that act as osmoprotectants, thanks to their ability to stabilize cellular proteins, providing a hydration shell and stabilizing their tertiary structures without interfering in cell metabolism (this is why they are called “compatible”). Indeed, compatible solutes not only provide protection from osmotic stress but some can also act as thermostabilizers, a property that has been exploited for biotechnological purposes.

There is a wide range of compatible solutes, but they can be classified into a few chemical categories (Empadinhas and da Costa 2008), such as amino acids and derivatives (including ectoines and hydroxyectoines), sugars and derivatives, phosphodiesteres, and polyols. Some of them, such as glycine betaine, are universally compatible solutes, while others are restricted to a specific group of microorganisms. For a detailed description of the chemical nature and occurrence of organic-compatible solutes within halophilic and halotolerant organisms, see Roberts (2005).

Recent work indicates that some microorganisms are able to combine the salt-in and compatible solute accumulation strategies depending on the environmental conditions (Deole and Hoff 2020).

Complex Organic Molecules

Kensei Kobayashi

Yokohama National University, Yokohama, Japan

Definition

In astronomy, complex organic molecules are defined as molecules with several carbon atoms such as benzene or acetic acid. These molecules have been detected in interstellar space using radio telescopes. A gas mixture of methane and nitrogen, for example, yields complex organic compounds upon UV irradiation or exposure to an electric discharge. These are sometimes referred to as ► [tholins](#), and they can be formed abiotically in the atmosphere of ► [Titan](#) (the largest satellite of Saturn).

In chemistry, “complex organic molecules” generally refer to much larger polymer-like molecules such as ► [proteins](#). Proteins are typical complex organic polymers, with well-defined three-dimensional structures, composed of 20 different amino acids. Given the immense possible variety of these polymers, they are indeed “complex.”

Keywords

Information · Computation · Complex
systems · Interactions · Non-reductionism ·
Scientific paradigm

Definition

There is no single definition of complexity (Edmonds 1999; De Domenico et al. 2019), as it acquires different meanings in different contexts. A general notion is the amount of information required to describe a phenomenon (Prokopenko et al. 2009), but it can also be understood as the length of the shortest program required to compute that description, as the time required to compute that description, as the minimal model to statistically describe a phenomenon, and more.

In general, complexity arises because of relevant interactions between the components of a system.

Overview

The study of complexity and complex systems is so broad and encompasses so many disciplines that it is difficult to define. There are different definitions suitable for different contexts and purposes. Etymologically, complexity comes from the Latin word *plexus*, which means interwoven. A complex system is one in which elements interact in such a way that it is difficult to separate their behavior. In other words, if one element affects the state of another element, the dynamics of the system cannot be *reduced* to the states of the elements, since interactions are relevant for the future state of the system. Interactions generate novel *information* that is not present in initial nor boundary conditions, so prediction is limited. Examples of complex systems include a cell, a brain, a city, the Internet, a market, a crowd, a pandemic, an ecosystem, a biosphere, and an atmosphere. A cell is composed of molecules, but the behavior and properties of a cell cannot be reduced to that of molecules. Their interactions generate constraints and information that is not present in molecules and determine the behavior of the cell.

Some approaches to complexity do not focus on its systemic aspect, but more on its probabilistic or algorithmic aspect. These are related to information theory, for example, how probable is a string of bits, how long is the shortest algorithm that produces a string of bits, what is the shortest time it can take an algorithm to produce a string of bits, or how compressible is a string of bits. Intuitively, in most of these descriptions, complexity represents a balance between order (stability) and chaos (variability) (Kauffman 1993), sometimes also described as criticality.

Since complexity can be found in almost any field, some people question its usefulness, while others defend it as a novel scientific paradigm that complements the traditional reductionist approach (Gershenson and Heylighen 2005; Morin 2006).

Basic Methodology

There have been several methods developed within the study of complexity that have proven to be useful, since they are able to take into account the interactions of the elements of a complex system (Sayama 2015). Tools include network science (Barabási 2016), agent-based modeling, cellular automata, genetic algorithms, and swarm intelligence.

Most of the complexity research is based on computer simulations. On the one hand, complex models tend to involve a large number of elements and/or interactions, which are difficult to handle without computer aid. On the other hand, interactions generate novel and relevant information that is not present in initial or boundary conditions. This makes it difficult to know *a priori* a final state of a system without computing all of its transitions, that is, predictability is limited. A model has to “run” before something definitive can be said about it. This is also known as *computational irreducibility*. Cellular automata provide a clear example of this. Thus, an equation-based approach is in many cases insufficient to explore the properties of a model.

There are many concepts that are related to the study of complexity, such as non-linearity, self-organization, adaptation, chaos, and emergence (De Domenico et al. 2019).

Key Research Findings

The scientific study of complexity has increased the understanding of phenomena in many different fields. Common examples include models of collective behavior, complex networks (molecular, metabolic, genetic, neural, trophic, ecologic, social, economic, organizational, political, geographical), non-linear dynamics, evolution, and distributed systems. Theoretically, complexity has also provided several concepts, formalisms, and tools. It has also contributed to emerging disciplines, such as digital epidemiology and computational social science.

The main difference between complexity-related and traditional techniques is that

complexity can easily include millions of variables into consideration, for example, with cellular automata, multi-agent systems, or networks. This is difficult to achieve with, for example, differential equations, which are more suitable for contexts where there are few variables considered and the state space or phase space does not change, that is, is stationary. The tools of complexity are suitable for studying non-stationary spaces, that is, those that change with time.

Applications

The scientific study of complexity and complex systems has found applications in physical, chemical, biological, computational/informational, social, economic, engineering, and other fields. In many cases, the concepts, tools, and methods of complexity have been applied to specific problems, for example, self-assembly, pattern formation, adaptive control, protein folding, ecological studies, robotics, evolution, etc. As such, many concepts from complexity have already been absorbed and used in several disciplines. In other cases, the study of complexity *per se* has also led to relevant research.

Complexity formalisms allow the study of phenomena at different scales and to relate them under the same framework. This is useful when multiple scales (spatial, temporal, functional, and dynamical) interact within a system, since the same language can be used to relate the scales. This is not feasible with a reductionist approach.

Future Directions

Some have speculated that complexity is a fad, and it will lose its popularity, following the steps of similar movements: cybernetics, catastrophe theory, and chaos theory. Nevertheless, complexity has been studied (under this name) since the 1980s, and everything indicates that the interest on it is growing. The concepts and methods that have been developed within the study of

complexity and complex systems are permeating into all disciplines. Maybe people will not use the term complexity, but this is not relevant. Complexity is helping shape a shift in the scientific worldview, from reductionist to “interactionist.” This is relevant since this shift is allowing us to expand the frontiers of our knowledge.

Composomes

Doron Lancet

Weizmann Institute of Science, Rehovot, Israel

Keywords

Prebiotic metabolism · Self-replication · Mutually catalytic sets · Selection · Evolution · Protocells · Vesicles

Definition

A composome is a quasistationary state in a dynamic description of compositional molecular assemblies (Segré et al. 2000). The term originated in the context of origin of life, in a monomer-world scenario (Shapiro 2007), proposed as an alternative to the RNA world. Composomes arise in an artificial chemistry description of early evolution, prior to the emergence of complex polymeric molecules such as RNA or proteins. This is a stage at which random assemblies of simple molecules might have acquired a prebiotic metabolism before exact polymeric replication existed. The dynamics of such molecular assemblies are thought to have been governed by processes such as catalytic closure, affording the emergence of mutually catalytic sets (Kauffman 1993) or a transition from a disordered to an ordered quasistationary state (Dyson 1999), both mimicking self-replication.

Overview

The specific computer-simulated model within which composomes have been invoked is the Graded Autocatalytic Replication Domain (GARD) model (Segré et al. 2000; Markovitch

and Lancet 2014). This model simulates assemblies of small molecules, typically lipids and other amphiphiles, that spontaneously accrete into discrete assemblies, much in line with Oparin's Conception of Origins of Life in a primordial soup environment. GARD is intimately linked to the concept of a Lipid World (Segré et al. 2001). This is an origin of life scenario that focuses on amphiphilic micelles and vesicles, in line with lipid protocells and other types of prebiotic protocells.

A key concept in GARD is that in a primordial soup, a huge diversity of amphiphiles has been available, so molecular assemblies could assume a large variety of compositions. The GARD chemical kinetics formalism shows that very specific compositions may breed true (with mutations), in a process of repeated accretion-driven growth followed by physical fission. Such favored compositions are defined as composomes, a name hinting at the idea that assemblies are capable of genome-like compositional information transmission from one generation to another. Composomes are a cornerstone of more recent studies that portray, among others, a route from metabolism-like composomes to genetic replication (Norris et al. 2012) and early ecology (Hunding et al. 2006; Markovitch and Lancet 2014). While some question the capacity of mutual catalysis-driven compositional assemblies devoid of informational biopolymer, to undergo selection and evolution (Vasas et al. 2010), solid evidence for the existence of such capacities has been reported (Markovitch and Lancet 2012).

The origin of life is ridden with a chicken or egg problem: present-day RNA and DNA are rather inert in the absence of catalytic proteins, and proteins cannot be formed without biopolymeric guidance. Composomes may be a clue as to where to look for a solution to this riddle (Shapiro 2007).

Argentina space agency

Definition

The “Comisión Nacional de Actividades Espaciales” (CONAE) is the space agency for Argentina. Argentina’s first activities in the space field date back to 1961, when the National Commission for Space Research (Comisión Nacional de Investigaciones Espaciales, CNIE) was first established within the Argentine Air Force area. With other local and international organizations, CNIE carried out, by means of rockets and stratospheric balloons, the first Southern Hemisphere scientific atmospheric studies, which included wind measuring and assessment of neutral atmosphere dynamics using the alkaline clouds technique. Together with the Argentine Institute of Aeronautics and Space Research, CNIE designed and constructed a family of one- and two-stage sounding rockets.

In 1991, the Argentine government decreed the creation of this National Commission for Space Activities as a civil organization. Since 1996, this specialized agency accomplishes its mission governed by the Ministry of Foreign Affairs.

CONAE is involved, in particular, in the use of space data for telemedicine and tele-epidemiology and the use of space infrastructure for health emergencies during disaster management.

In January 26, 2016, CONAE was transferred to the scope of the Ministry of Science, Technology and Productive Innovation. The agency is working under a long term plan The national plan for Space 2016–2027.

Concentration Gradients

David Deamer
Department of Biomolecular Engineering,
UC Santa Cruz, Santa Cruz, CA, USA

Keywords

Membrane potential · Semipermeable membrane · Stored energy

Definition

Concentration is a measure of the amount of solute in a solvent, typically expressed in units of moles per liter. A 1.0 molar solution (abbreviated 1.0 M) contains 1 mole of a solute in 1 liter of total volume. A concentration gradient exists when a higher concentration of a solute is separated from a lower concentration, by a semipermeable membrane.

Overview

Concentration gradients of solutes are common in living cells and are essential sources of energy for all forms of life. Concentration gradients are generated and maintained across biological membranes by ion pump enzymes that transport ionic solutes such as sodium, potassium, hydrogen ions, and calcium across the membrane. Energy is required to produce a gradient, so the gradient is a form of stored energy. An important example is the sodium and potassium ion gradient across most cell membranes, which produces the resting potential and action potentials of excitable membranes like those of neurons. Hydrogen ion gradients are generated by the electron transport systems embedded in membranes, either as a pH gradient or a ► [membrane potential](#). For instance, a gradient equivalent to 210 mV or 3.5 pH units (~1000-fold gradient) is the source of energy driving ► [ATP](#) synthesis in mitochondria, chloroplasts, and bacterial membranes. Although concentration gradients are essential to life today, it is uncertain what role they may have played in the origin of life. Early membranes were likely to be relatively permeable to solute ions, so that primitive cells would be unable to use gradients as an energy source.

Concretions (Mars)

Alessandro Airo

Institut für Geologische Wissenschaften Tektonik und Sedimentäre Geologie, Freie Universität Berlin, Fachbereich Geowissenschaften, Berlin, Germany

Definition

Concretions are postdepositionally cemented areas within sedimentary rocks that occur as spheres, disks, tubes, botryoidal aggregates, or have an irregular lumpy shape. The cement forms through precipitation from pore water and is usually composed of carbonate (e.g., calcite, siderite), sulphate (e.g., gypsum), silica (e.g., chert), or iron oxide (e.g., hematite). Nodules have a similar origin, but instead of cementing the pre-existing sediment in place, they substitute the particles through relocation or dissolution.

The Mars Exploration Rover Opportunity was the first to discover concretions on Mars, the so-called ‘blueberries’, which are cemented by hematite (Squyres et al. 2004). The Mars Science Laboratory Curiosity has discovered light-toned concretions within mudstones at Gale crater, which possibly are cemented by sulphates (Grotzinger et al. 2014). The occurrence of concretions on Mars is insofar of interest to astrobiologists as they indicate the former presence of groundwater.

Condensation Sequence

Avi M. Mandell

NASA Goddard Space Flight Center, Greenbelt, MD, USA

Keywords

Cosmochemistry · Solar nebula

Definition

In planetary science, the condensation sequence refers to the order in which chemical compounds transition from gas to solid phase in a protoplanetary nebula (disk), based on the condensation temperature of each compound. The condensation sequence is important because the temperature of a protoplanetary nebula varies radially and temporally, and the chemical composition and mass of any bodies formed at a given place and time is defined by the materials that can condense at the local temperature.

Overview

Condensation is defined as the process by which chemical materials change phase from the gaseous or liquid phase to the solid phase. Chemical condensation occurs within a narrow range of temperature specific to each individual chemical compound (a few tens of degrees), defined by

the abundance of the elements in the nebular gas and the molecular structure and composition of the solid compound. Effective condensation temperatures depend on the local environment (i.e., pressure) and can be lowered by including catalytic reactions (i.e., grain growth reactions). A “condensation sequence” orders a specific list of chemical compounds of interest by their condensation temperatures, in order to determine which materials will condense in a medium of a specific temperature.

The Solar System is thought to have formed from a rotating disk of gas and dust called the ► “[solar nebula](#)” (this is true for other planetary systems as well; we call these disks “protoplanetary disks”). The temperature of the solar nebula varied both radially (from the inner regions of the disk to the outer regions) and vertically (from the midplane to the surface) due to heating from the Sun and viscous heating at the midplane. The temperature in different parts of the solar nebula also changed over time as the disk material was depleted due to accretion to the star and photo-evaporation. The material condensing out of the gaseous solar nebula into grains and larger bodies would therefore be a function of both location and of age, resulting in a changing chemical composition of bodies over space and time in the nebula. A typical condensation sequence of the nebular gas starts with refractory oxides and silicates (1,700–1,400 K), followed by iron and nickel which will eventually segregate into planetary cores and the silicates of their future mantle and crust (1,350–1,150 K). Alkali elements and sulfide-loving (chalcophile) elements such as Cu, Zn, and Pb and finally volatile elements such as S, C, N, and H₂O join between 600 and 100 K. The temperature at which condensation came to a halt for the material of a planetary body, therefore, defines its depletion in volatiles, among them water.

One of the most interesting consequences of the condensation sequence is therefore the proposed existence of a ► “[snow line](#)” in the solar nebula. The snow line is defined as the radial location in the solar nebula beyond which the local temperature of the nebula drops below the condensation temperature of water. Bodies formed beyond this boundary would contain

water, while bodies inside this boundary would be relatively waterpoor. In fact, Earth is thought to have formed inside the snow line, hence, the concept of “water delivery”. The existence of water ice beyond the snow line has increased the solid surface density at these locations and led to the rapid growth of the giant planets’ cores.

Condensation Temperature

William M. Irvine

University of Massachusetts, Amherst, MA, USA

Definition

The condensation temperature is that at which a given gas-phase constituent condenses into a liquid. This temperature depends on the physical and chemical state of the system.

Conjugation

Carlos Briones

Centro de Astrobiología (CSIC/INTA), Consejo Superior de Investigaciones Científicas, Madrid, Spain

Definition

In microbiology, conjugation is the process by which two individuals of the same – or even different – species exchange their genetic material during a temporary union. Among ► [bacteria](#), conjugation is a widespread mechanism that allows the transmission of one conjugative

► [plasmid](#) from one cell, called “donor,” to another, the “recipient,” through the physical contact between them. Conjugative plasmids carry genes that promote bacterial conjugation and are frequently involved in ► [lateral gene transfer](#) – also called horizontal gene transfer, HGT – between individuals of different species. For example, antibiotic resistance or the ability to metabolize a new organic molecule can be transmitted by conjugation among microorganisms. In the majority of bacteria, conjugation is not a standard mode of reproduction as it is the case in sexual organisms. In turn, in certain ► [protists](#) such as paramecia, although they usually reproduce asexually by fission, conjugation is a sexual process of reproduction between individuals of opposite mating types. Conjugation is also used as a genetic engineering technique in the lab.

Continental Crust

Nicholas Arndt
Maison des Géosciences, LGCA, Université
J. Fourier, St-Martin d'Hères, France

Definition

Continental crust is that portion of the Earth's ► [crust](#) composed mainly of low-density siliceous (granitoid) rocks. It represents about 70% (volume) and 40% (surface) of whole Earth crust and underlies most of emerged land. Its average thickness is ~30 km and varies from ≤10 km in rifts to up to 80 km beneath mountain belts. Dominant constituents are granitic rocks and their metamorphic equivalents (gneiss) and meta-sedimentary or metavolcanic sequences. Continental crust forms above ► [subduction](#) zones and contains a large proportion of the Earth's budget of incompatible trace elements and heat-producing elements. The presence of continental crust is a signature of ► [plate tectonics](#) that distinguishes ► [Earth](#) from other planets.

The continental crust is made of low-density material (granitoid $d \approx 2.7$) while the oceanic crust (basaltic $d \approx 3.0$) is denser. Consequently, the presence of continental crust in lithospheric segments confers to them more buoyancy, such that, due to Archimedes' principle, they float higher on the asthenosphere than those without it. Its average altitude above sea level is of 870 m, so that, liquid water usually only covers its margins

(“continental margins,” shelves). Such a situation allows there the biological colonization of regions covered by shallow water and within the photic zone. This gives rise to the “carbonate factory” on continental shelves.

Subduction

Synonyms

[Continental lithosphere](#); [Continental plate](#); [Continental tectosphere](#)

Definition

On a planet with ► [plate tectonics](#), continents are the topographic expression of emergent, buoyant, strong, and cool plates, contrasting with thinner, denser and hotter oceanic plates covered by water. A relatively thin crust (mostly 25–45 km) and an underlying much thicker subcontinental ► [mantle](#) (150–250 km) together form the continental lithosphere that moves as a coherent unit. Together they have the capacity to withstand destructive convective forces for billions of years. The uppermost crust is highly enriched in many incompatible trace elements, including the sources of radioactive heat (i.e.; ^{238}U , ^{235}U , ^{232}Th , ^{40}K). Where continents collide with other plates, their edges thicken to form mountain belts, which eventually erode to fill sedimentary basins.

Overview

From a geological perspective, large expanses of land – continents – are an expression of the greater buoyancy of continental plates compared to oceanic plates. Continental plates consist of an upper layer, the ► [continental crust](#), which on Earth is typically 35 km thick, and a lower layer, called the subcontinental lithospheric mantle, which on Earth can reach as deep as 250 km. The density of both layers is lower than that of typical convecting upper mantle, resulting in a negative gravity anomaly over continents (Barrell 1914).

► [Radiogenic isotopes](#) demonstrate that the two layers are formed contemporaneously during subduction of oceanic plates (e.g., Nägler et al. 1997).

At depth, where subducted ► [oceanic crust](#) experiences ► [metamorphism](#), hydrous fluids are released and rise up into the overlying mantle, allowing a partial melt to form, which preferentially consumes the denser mantle minerals and also incorporates many (incompatible) chemical elements that are not favored by mantle minerals. This leaves behind a less dense residue that is depleted in many trace elements, among others, in the radioactive heat producers (U, Th, K). Such subcontinental lithospheric mantle acts as a buoyant, strong, cool protective root for continental crust (e.g., Kamber and Tomlinson 2019). The melt itself rises to the ► [Moho](#) (the boundary between the Earth's crust and mantle) and differentiates into the continental crust, which is also buoyant and chemically very different from the bulk planet (Taylor and McLennan 1985). The buildup of radioactive heat in the crust leads to chemical stratification, typically culminating in an event of widespread granite emplacement (cratonization) after which the new crust achieves full mechanical stability (Sandiford and McLaren 2002).

On Earth, continents have an average age of ca. 2.2 billion years; the oldest continental fragments are about 3.85 billion years old. Such antiquity is testimony to the thermal and mechanical stability of continents (e.g., Peslier et al. 2010).

The familiar concept of continents surrounded by ocean basins may only be valid on planets whose interiors cool via the plate tectonic process. Furthermore, as a result of relative plate motion, the continental plates (which cannot be destroyed by subduction processes) can thicken and deform along their edges, leading to the formation of mountain belts. Continents on young planets with higher crustal heat production have less mechanical strength and lower topography, whereas mid-aged planets, like Earth, have continents capable of supporting rapid vertical movement. Amalgamation of several continental plates produces ► [supercontinents](#), whose breakup is typically triggered by thermal erosion of the subcontinental lithospheric mantle by heat upwellings from the deeper mantle (mantle plumes; McKenzie and Bickle 1988).

Large sedimentary basins that accommodate erosion products of mountain belts either express the thinning of the underlying continental lithosphere (rift basins and passive margins), thermal doming followed by erosion and subsequent cooling (intraplate basin), or flexural loading of lithospheric margins (e.g., foreland basins).

Convection, Stellar

Steven W. Stahler
Department of Astronomy, University of
California, Berkeley, CA, USA

Definition

Convection is the transport of heat by turbulent motion of gas. Within stars, this thermal energy

is supplied either by nuclear fusion or bulk gravitational contraction. The luminosity of the Sun is carried outward by convection in the outer third of its radius. The shifting pattern of granulation visible on the solar surface represents rising and falling gas cells in the convection zone. The upwelling of gas in this zone, together with the Sun's rotation, amplifies and maintains the solar magnetic field. When the Sun was a ► [pre-main-sequence star](#), its relatively high surface cooling drove convection throughout its interior.

Overview

Stars generate energy by nuclear fusion or gravitational contraction. This energy is transported through the interior, eventually streaming outward as radiation from the surface. The transport occurs either through the diffusion of radiation or convection. In the Sun, whose luminosity stems entirely from fusion, convection operates in the outer third of the radius. This zone is a remnant from the Sun's pre-main-sequence epoch, when it was entirely convective.

Convection occurs through upwelling of gas cells. The hot cells are buoyant and rise toward the surface, expanding and releasing energy by radiation. The cooled cell, now denser, falls back down, where it is reheated by the star's energy source. The cycle then repeats itself in a circulating pattern of motion. Convection only occurs if the specific entropy (entropy per unit mass) of the gas declines toward the surface. In regions where the entropy rises, fluid cells can rise temporarily, but then quickly fall back down and thereafter oscillate. Net energy transport in such regions occurs through radiative diffusion.

The specific entropy inside a star falls if the object is either heated from below or cooled from above. The first mechanism operates in main-sequence stars, where hydrogen fusion generates energy in the central region. The second mechanism operates in pre-main-sequence stars. These stars have such large radii that surface cooling alone drives convection throughout the interior.

The upwelling of convective eddies in the Sun is visible directly in the ever-changing pattern of granulation near the surface. It is a combination of this upward motion and the Sun's internal rotation that creates the star's magnetic field. This field, in turn, channels the solar wind and provides a braking mechanism for the star's rotation. This general idea is confirmed by observations of other main-sequence stars. Those with outer convection zones rotate much more slowly than stars lacking them.

The rise and fall of cells, while it has an overall order, is also a somewhat chaotic process. In this regard, convection is similar to other forms of fluid turbulence, all of which are difficult to treat in a quantitative manner. The most successful approach is the *mixing-length theory*. Models of stellar interiors that use the mixing-length theory accurately reproduce the chief properties of main-sequence stars, including the depth of the convection zone itself.

Cool Early Earth

Nicholas Arndt
Maison des Géosciences, LGCA, Université
J. Fourier, St-Martin d'Hères, France

Synonyms

[Early Earth](#)

Definition

The term “Cool Early Earth” refers to the new vision of the ► [Hadean](#)-early Archean Earth characterized by much more temperate surface conditions than believed before. The term was coined by the American geochemist John Valley in 2002. A popular image of the early Earth is indeed, that of a planet covered by hot magma and subjected to an intense meteoritic bombardment. This image is at the origin of the term Hadean (from the Greek god of the underworld, Ἅδης = *Hades*) for the first eon. The fractionated oxygen isotopic compositions of 4.4–4.3 Ga-old Jack Hills zircons indicate, however, that they crystallized from magma that had been in contact with water or sediments; thus, surface temperatures may have been low enough to permit liquid water on the Earth's surface. It is therefore possible that liquid water was present at the surface of the Hadean Earth and that Earth cooled rapidly from its “hot phase” during and soon after core formation.

Overview

The chemical composition of the 4.4–4.3 Ga Jack Hills zircon crystals implies that they crystallized from granitic magma. Consequently, as granitoids are the main components of continental crust, it can be concluded that this later existed as early as 4.4 Ga ago (Wilde et al. 2001). However, the existence of continental crust does not necessarily imply that continents emerged above sea level. The genesis of granites requires that water was transported into the mantle, perhaps by subduction of hydrated oceanic crust. This implies that oceans were present at the surface and that ► [plate tectonics](#) operated. The presence of oceans, in turn, allows speculation that life could have been present at that time. Metamorphosed sedimentary rocks and ► [pillow lavas](#) in 3.8 Ga-old strata from the ► [Isua Supracrustal Belt](#) (West Greenland) provide evidence of liquid water and temperate conditions in the early Archean.

It is commonly accepted that the Sun was less luminous in the first part of Earth history, 25–30% less than today during the Hadean and early

Archean (Sagan and Mullen 1972; Goldblatt and Zahnle 2011). This should have resulted in extremely cold conditions at the surface of the Earth and other terrestrial planets. The probable mechanism to generate temperate surface conditions is the atmospheric presence of a high proportion of greenhouse gases such as CO₂ and CH₄, combined with some sort of internal regulation that maintained their concentrations at the levels needed to preserve clement conditions at the surface (the so-called Faint Young Sun Paradox).

Definition

An astronomical coordinate system is a set of three orthogonal directions, an origin, and a choice of mathematical coordinates within this system, with respect to which the position and motion of celestial bodies are referred.

Overview

Motion and position are not absolute concepts and must be described with respect to some reference. In astronomy, this is a reference frame, that is to say the realization of a set of axes with the means to assign coordinates to an object. Since these axes are not given a priori on the celestial sphere, one must use existing celestial bodies or directions to define the coordinate system. In this context, it is important to draw attention to the difference between a reference system and a reference frame. A reference system is the set of prescriptions stating how a celestial coordinate system is to be formed. It defines the origin and fundamental planes (or axes) of the coordinate system, together with the constants and models necessary to fully define the system. A reference frame consists of a set of identifiable points on the sky, together with their coordinates, which serves as the practical realization of a reference system.

A system of axis is determined by the choice of an origin and of three mutually orthogonal directions labeled by the unit vectors e_1 , e_2 , and e_3 . With the underlying assumptions of absolute Euclidean space, the orientation of the system does not change when translated between two origins, meaning that the choice of the origin and directions are independent of each other. The commonest origins are the location of the observer (topocentric frame), the center of the Earth (geocentric frame), the barycenter of the solar system (barycentric frame), and the center of the Galaxy (the galactic frame). The center of a planet or a satellite can be used as well for specific purposes. The set of three directions is constructed by selecting the polar direction e_3 , or equivalently by selecting a fundamental plane going through the origin, and a direction e_1 in this plane for the x -axis. A point M is then represented by the Cartesian coordinates in this frame or by spherical coordinates. The latter are more convenient to represent directions on the celestial sphere and are widely used in observational astronomy or to construct stellar catalogues and ephemerides of low accuracy. Cartesian coordinates are preferred to model motions in the solar system and to produce accurate ephemerides with position and velocity vectors. The choice of the

fundamental directions is dictated by the necessity to make them accessible to observation, so that the system is materialized in space. This leads to the following usual systems, appearing in most astronomical work.

- The horizon coordinate system uses the observer's local vertical as a fundamental direction or equivalently the local horizon as a fundamental plane. This is a physical definition that can be accessed with a plumb line or a spirit level. The pole overhead is the zenith, and the one diametrically opposite is the nadir. The two angles that specify the spherical coordinates are the azimuth angle (A) and the altitude (h). The azimuth is measured in the horizontal plane from one of the two points of intersection of the celestial meridian with the horizon. The altitude is the angular height of a point with respect to the horizon, counted positively above the horizon and negatively below. Instead of altitude h , its complement measured from the zenith, the zenith distance z , is also frequently used.
- In the equatorial coordinate system, the primary direction is defined by the Earth's spin axis, giving the ► [celestial equator](#) (the projection on the sky of the Earth's equator) as fundamental plane. The reference point on the celestial equator is the vernal equinox, the direction on the celestial sphere at which the Sun, in its yearly path around the celestial sphere, crosses the equatorial plane moving from south to north. The ► [declination](#) (δ) of a body is its angular distance north or south of the equator, and the ► [right ascension](#) (α) is its angular distance measured eastward along the equator from the equinox. Because both the celestial equator and the ► [ecliptic](#) are moving (precession of the equinoxes), the coordinate systems that they define must be specified at a particular date. In contrast, the ICRF (International Celestial Reference Frame) has fixed directions determined by the positions of a set of extragalactic sources observed in radio interferometry, with an origin at the barycenter of the solar system. However, these axes correspond closely to what would conventionally be described as the equator and equinox of

J2000.0 and therefore to the equatorial system at this epoch. For application with accuracy requirement less than 0.1 arcsec, the distinctions between ICRS and the conventional definition are not significant. The subset of the single stars of the Hipparcos Catalogue is a secondary realization at optical wavelengths and is designated as the HCRF (Hipparcos Celestial Reference Frame).

- Of less importance are the ecliptic system, using the mean orbital plane of the Sun as fundamental plane with origin at the vernal equinox, and the galactic coordinate system defined by arbitrarily assigning equatorial coordinates for the pole and the origin in the galactic equator, nominally close to the galactic center. In the ICRF, the galactic pole is near $\alpha_p = 192.75^\circ$, $\delta_p = 27.13^\circ$, and the galactic center is located at about $\alpha_p = 266.40^\circ$, $\delta_p = -28.93^\circ$.

Copernican Principle

David Dunér
Lund University, Lund, Sweden

Keywords

Cosmology · Heliocentric Worldview · History of Science · Philosophy of Science

Synonyms

[Cosmological principle](#); [Mediocrity principle](#)

Definition

The Copernican principle states that Earth has not any privileged position in the universe. In astrobiological terms, it means that terrestrial life, including the human beings, has not any particularly privileged, special, or unique position in the universe, which leads to the assumption that, given the presence of life on Earth, life will exist also in other places in the universe.

History

The term Copernican principle was first coined by the cosmologist Hermann Bondi in 1952. The principle refers to the Polish astronomer Nicolaus Copernicus (1473–1543), who, in his book *De revolutionibus orbium coelestium* (On the Revolutions of the Celestial Spheres) from 1543, proposed a heliocentric model for the explanation of the movements of the planets. The consequence of placing the Sun instead of the Earth in the center of our planetary system was that Earth no longer had any particularly privileged position within this planetary system. Earth became a planet among other planets. There was not any fundamental difference between Earth and the Heavens, the sublunar world, and the supralunar world as the Aristotelian-Scholastic philosophy maintained. This opened up the possibility of life on other planets. According to the Ptolemaic geocentric model and Aristotelian physics extraterrestrial life was unlikely, due to Earth's privileged position in the center of the universe and the physical laws of the elements. But, if Earth is just a planet among other planets, and as Giordano Bruno claimed, that every star has its own planetary system, there might be countless other living planets out there. If the living Earth is a rather common, mediocre place in universe, why should not also other planets harbor life? In the seventeenth and eighteenth century, many leading astronomers and philosophers have relied their

arguments on the Copernican principle, for example, Bernard le Bovier de Fontenelle and Christiaan Huygens. The presumed existence of extraterrestrial life was very much a question of how similar those potential life-bearing places must be to Earth. The answers varied, for some interpreters it was just enough that it was a planet orbiting a star, but others added a number of considerations such as temperature, presence of water, atmosphere, rocky surface, etc.

Overview

In astrobiology, the Copernican principle has been extended to the biological realm, to the question of the existence of life elsewhere in the universe. Given the existence of planets similar to ours, the mediocrity claims of the Copernican principle fuel expectations of finding life beyond Earth. In that sense, the Copernican principle lies historically behind much of the astrobiological endeavor.

The Copernican principle is sometimes used interchangeably with the related principles, the Mediocrity principle and the Cosmological principle. The Mediocrity principle suggests that there is nothing special or unusual with the evolution of the solar system and the formation of Earth, as well as the evolution of life on Earth. This means, given the existence of life on Earth, and that there are many such mediocre Earth-like planets out there, it would not be unlikely if these or some of these planets also harbor life. The Cosmological principle, on the other hand, states that humans are not privileged observers in the universe. Universe is isotropic and homogeneous, and then would look pretty much the same irrespectively from where one observes it. Contrary to the Copernican principle stands the trend of explaining the rarity and specialness of our place and our existence, the fine-tuned universe, that the existence of life rests on the exact value of certain physical constants. If the value of these constants had differed only slightly from the present ones, the evolution of the universe would have taken another path and life as we know it would not have emerged.

The Copernican heliocentric worldview had far-reaching consequences for the view of the

human being and its place in the creation. The human being was not the center of the universe, everything was not orbiting around her, which challenged the teachings of the Scripture. The Copernican principle thus leads to a retreat of an anthropocentric view of the universe. It could be extended further from the Earth. Our solar system has no particularly unique location in the Milky Way, it moves around the center of the galaxy along with many other stars and their planets. Our galaxy itself is, as Edwin Hubble showed, just one among many other galaxies in the universe. Even the entire universe may be only one among many others in a multiuniverse. Carl Sagan sums up this dethronement of the human being from the center of the universe, in *Cosmos* (1980) he says: “We find that we live on an insignificant planet of a humdrum star lost in a galaxy tucked away in some forgotten corner of a universe in which there are far more galaxies than people.” The Copernican principle can not only be used for our spatial position, but also to our temporal position. Bondi himself coined the term in order to support his steady-state cosmology. We, who now observe the universe, do not live in any special or unique moment in time, in the history of the universe, neither in the beginning nor at the end of time. We humans are also rather mediocre in magnitude, far smaller than galaxies and far larger than atoms. But we human beings are the only ones, so far we know, who are aware of this mediocrity – that is, one might say, the paradox of the Copernican principle.

Copper Isotopes

Ernest Chi Fru

Centre for Geobiology and Geochemistry, School of Earth and Ocean Sciences, Cardiff University, Cardiff, UK

Keywords

Copper and life · Copper and proteins: copper isotopes and atmospheric evolution · Copper isotopes and environmental redox chemistry

Definition

Copper (Cu) has two isotopes: ^{63}Cu and ^{65}Cu . Both are stable, with natural abundances of 69.174% and 30.826%, respectively (Albarède 2004). The distribution of these Cu isotopes in nature is defined by the equation: $\delta^{65}\text{Cu} = [(^{65}\text{Cu}/^{63}\text{Cu})_{\text{sample}} / (^{65}\text{Cu}/^{63}\text{Cu})_{\text{standard}} - 1] \times 1000$.

Overview

Cu is a transition metal that rarely occurs in its native form (Cu^0) (Dekov et al. 2013). It is, however,

abundant in oxygen-poor environments as Cu^+ and Cu^{2+} when conditions are partially to fully oxygenated (Chi Fru 2011; Dekov et al. 2013; Moynier et al. 2017). The oxygen-driven transformation of Cu results in isotopic fractionation between precipitated minerals and the solutions from which they formed (Zhu et al. 2002; Ehrlich et al. 2004; Dekov et al. 2013; Moynier et al. 2017). Cu readily binds to sulfide, leading to Cu being hosted by sulfide minerals in differentiated magmas and volcanic rocks, but rarely in the silicate mineral phases that make up a bulk of volcanic rocks (Albarède 2004).

The Cu minerals in volcanic rocks weather as a function of oxygen availability to form soils and sediment minerals. This quantifiable relationship between rock Cu minerals and oxygen-driven weathering has been used to link Cu to the permanent rise of oxygen in Earth's atmosphere during the so-called Great Oxidation Event (GOE) that occurred ~2.45 billion years ago (Chi Fru et al. 2016). At this time, atmospheric oxygen rose from below 10^{-5} present-day levels and climbed to at least 10% of the modern value (Lyons et al. 2014). It is thought that the replacement of terrestrial detrital iron sulfide-rich beds by iron (oxyhydr) oxide-rich layers after this time was a result of the progressive oxidation of the sulfide minerals as appreciable amounts of oxygen became a permanent fixture of the atmosphere (Holland 2006). The evidence shows that the oxygen weathered and transformed a major sulfide reservoir that had accumulated on the continents in the absence of oxygen in the atmosphere before 2.45 billion years ago (Canfield 1998; Konhauser et al. 2011).

As a corollary, the weathering of Cu sulfides on land discharges fluids enriched in heavy ^{65}Cu (Moynier et al. 2017). This is consistent with the enrichment of ^{65}Cu in modern, sulfate-rich seawater and sediments (Dekov et al. 2013; Takano et al. 2014; Moynier et al. 2017). In addition, the binding of Cu by iron (oxyhydr)oxide minerals precipitating from the water column removes heavy ^{65}Cu from solution (Pokrovsky et al. 2008; Balistrieri et al. 2008). It is, therefore, believed that a change in the isotopic signature of Cu in marine, organic carbon-rich sediments following the GOE was impacted by the weathering of continental sulfide minerals and the difference in the volume of banded iron

Copper Isotopes, Fig. 1 (a) Conceptual model for the fractionation of Cu isotopes in anoxic and oxic atmospheres linked to the weathering of continental sulfide minerals, adsorption by iron (oxyhydr)oxides and biological

incorporation into biomass. (b) Cu isotope fractionation and preservation in organic carbon-rich sediments deposited under oxygen-poor and oxygen-rich atmospheres before and after 2.5 billion years ago (Chi Fru et al. 2016)

formation (BIF) that was precipitated before and after the GOE (Fig. 1).

Living cells incorporate light ^{63}Cu into biomass (Zhu et al. 2002; Navarette et al. 2011). This has particular implications for biological complexes and enzymes that catalyze important biogeochemical processes, including aerobic methane, iron, and ammonia oxidation, the reduction of nitrate to nitrogen gas, and some aspects of photosynthesis (Zahn et al. 1996; Zumft 1997; Chi Fru 2011; Chi Fru et al. 2011; Ilbert and Bonnefoy 2013).

Taken together, the conceptual model presented in Fig. 1 suggests that the redox sensitivity of Cu makes it a robust biogeochemical tool for remotely identifying worlds with atmospheric compositions of the past, present, and future that can sustain Earthlike life forms. This important criterion arises from the ability of Cu isotopes preserved over long geological timescale in rocks that interacted with the atmosphere and biosphere to differentiate the oxygenation state

in which they formed. Because oxygenation is primarily a strong property of the *Oxyphotobacteria* that invented oxygen-producing photosynthesis, it is an expressed signature for Earthlike life conditions.

Core Accretion, Model for Giant Planet Formation

Sean N. Raymond

Laboratoire d’Astrophysique de Bordeaux,
CNRS, Université de Bordeaux, Bordeaux,
France

Definition

Core accretion is the standard model for giant planet formation. The core accretion model proposes that the formation of ► [giant planets](#) starts with core formation followed by gas accretion. First, small bodies continually collide to form larger ones, eventually reaching the stage of protoplanetary cores, which are essentially large ► [planetary embryos](#) that form in the giant planet region. Cores that reach masses of a few Earth masses begin to accrete gas from the ► [protoplanetary disk](#), slowly at first, and then at a runaway rate when the gaseous envelope’s mass becomes comparable to the core mass. Cores, therefore, represent the “seeds” of gas giant and ice giant planets in this model. An alternative model for giant planet formation is disk instability that proposes that giant planets form via a local gravitational collapse in the disk, which can later be followed by core formation and accretion of solids.

Planets · Satellites

Synonyms

[Planetary core](#)

Definition

The core is the central spherical region of a ► [planet](#). In a ► [terrestrial planet](#), it consists of an iron-rich alloy. In a satellite, the core may be composed of a mixture of iron, silicates, and ice depending on the degree to which the satellite interior is differentiated (see “► [Differentiation, Planetary](#)”). In a ► [giant planet](#), the core is made of a similar mixture of iron, ► [rock](#), and ice albeit at much larger pressures and temperatures.

Overview

The interiors of planets and satellites are differentiated to varying degrees with the heaviest materials at the center. The degree of differentiation in solid planets and satellites depends on their thermal histories since differentiation requires at least partial melting at some early epoch. Cosmochemical and physical models of the planets and satellites suggest the existence of cores and provide estimates of their sizes and masses. An iron-rich core has been proven beyond doubt for the ► [Earth](#) by the inversion of seismic and gravity data. The Earth's core is composed of a Fe-Ni alloy but also contains a small fraction (<10%) of lighter elements such as Si, O, or S and is layered with a liquid outer core and a solid inner core. (See Rabinowicz et al. (2015) for reviews on the interior structure of the Earth and Olsen and Schubert (2015) for reviews on the Earth's core dynamics.) It is widely agreed that the inner core is the result of core freezing and that it grows as the planet cools. It is also widely agreed that the energy liberated upon core freezing powers the generation of its ► [magnetic field](#) through a dynamo. ► [Mars'](#) core is inferred from gravity data and the chemistry of the ► [SNC meteorites](#) (Sohl and Schubert 2015 for a review). Its density, chemistry, and the absence of a present-day magnetic field suggest that the core is completely liquid (Schubert and Spohn 1990). The cores of ► [Venus](#) and ► [Mercury](#) are constrained by the average densities of these planets and cosmochemistry. Venus is thought to have a core approximately as large as the Earth's. The large average density of Mercury along with the recent gravity and libration data gathered by the Messenger mission suggests that the core is unusually large with a radius of about 0.8 planetary radii or about 1,800 km (Smith et al. 2012) and a solid inner core. Recent reanalysis of Apollo seismic data by Weber et al. (2011) suggests that the Moon has a solid inner core with a radius of 240 ± 10 km surrounded by a fluid, iron-rich outer core of 330 ± 20 km. The interpretation of the data suggests a partially molten zone in the rock mantle above the core of 480 ± 15 km. A solid mantle and a crust complete the lunar

interior structure. The gravity fields measured at the Galilean satellites of ► [Jupiter](#) suggest that ► [Io](#), ► [Europa](#), and ► [Ganymede](#) have iron-rich cores (e.g., Schubert et al. 2004). This is particularly true for Ganymede for which the magnetic field suggests a liquid iron-rich core with possibly a solid inner core. ► [Callisto](#) and ► [Titan](#) (Iess et al. 2010), as the data suggest, are incompletely differentiated and likely have large cores composed of ice, silicates, and possibly iron or iron oxides. The gravity fields of Jupiter and ► [Saturn](#) suggest cores consisting of ice, silicates, and iron, but their masses and, in particular, their radii are uncertain (Guillot and Gautier 2015 for a review). Estimates range from a few to about ten Earth masses. Uranus and ► [Neptune](#) may have similar cores, but interpretations of the gravity field suggest that the layering in the interiors of the latter two planets is less pronounced than in Jupiter and Saturn. Rather, density and composition change with depth more gradually (Podolak et al. 1995).

Corona Discharge

Henderson James Cleaves
Earth-Life Science Institute (ELSI), Tokyo
Institute of Technology, Tokyo, Japan
Blue Marble Space Institute of Science,
Washington, DC, USA
Center for Chemical Evolution, Georgia Institute
of Technology, Atlanta, GA, USA

Definition

A corona discharge is a positive or negative electrical discharge created by the ionization of a gas surrounding a conductor, for example, a mineral surface, which occurs when the strength of the

electric field exceeds a certain threshold value. A charged ► [plasma](#) is created around the surface generating ions, which dissipate their charge to proximal areas of lower potential or recombine to form neutral molecules. If the ionized region continues to grow instead of quenching, a momentary spark or a continuous arc may result. A neutral atom or molecule of the medium, in a region of strong electric field, may be ionized, for example, by the absorption of a photon, to create a positive ion and a free electron. The electric field around the surface may then separate these charged particles and prevent their recombination. As a result of the acceleration of the electrons, further electron/positive-ion pairs may be created when they collide with other neutral atoms. These then undergo the same processes creating a cascade of electrons.

Such energetic processes may have contributed to prebiotic synthesis, providing electrical energy similar to the electric discharge used in Miller-Urey-type experiments. Corona discharges are estimated by some to discharge some three times the energy of lightning strikes on the present Earth (Miller & Cleaves 2006), and this ratio may have been similar on the primitive Earth.

Corona, Coroneae

Jörn Helbert
DLR, Institut für Planetenforschung, Berlin,
Germany

Definition

Coroneae are volcano-tectonic landforms only seen on the planet ► [Venus](#). They are oval to

circular features typically 100–300 km in diameter. A few of the coronae are even larger. They have a circular or nearly circular, tectonically deformed annulus, which usually stands a few hundred meters above the surrounding plains. The area inside the annulus is typically lower than the surrounding plains and has been flooded with plains-forming volcanic lava. Aprons of young lobate (tongue-shaped) volcanic flows are seen radiating from many coronae. At the center of some coronae one finds the corona core, an elevated and tectonically deformed area.

Coronagraphy

Daniel Rouan
LESIA, Observatoire Paris-Site de Meudon,
Meudon, France

Definition

Coronagraphy designates the group of optical techniques that aim at suppressing or reducing the halo of light that surrounds the image of a star, in order to detect faint structures like a circumstellar disk or companions, especially exoplanets. It was invented in 1930 by the French astronomer Bernard Lyot (Fig. 1) to study the Sun's corona, the extremely faint emission from the region around the Sun, at times other than during a solar eclipse. The coronagraph is in its simplest form an occulting disk in the focal plane of a telescope combined with a mask in a plane optically conjugated to the entrance aperture, so that the image of the solar disk is blocked and the stray light reduced by a large factor. Since then, the term has been kept for research in areas other than the solar corona and designates now any optical system able to block as much as possible the glare of a star to allow detection of companions or disk structures in its immediate vicinity.

Coronagraphy, Fig. 1 Bernard Lyot, a French astronomer who invented the coronagraph, an optical instrument whose original purpose was to study the faint extended emission around the Sun, the so-called corona

Overview

The ability to directly image an extrasolar planet – that is, to separate the light emitted or reflected by its surface or atmosphere from that of the star it orbits – offers the greatest prospect for characterizing these objects. Direct ► [imaging](#) gives the possibility of determining the colors and spectra of planets, in a way independent of their orbital inclination. This information allows astronomers to distinguish between gas giants, ice giants, and Earth-like planets under a variety of circumstances such as distance from the star, age, etc. Direct imaging also allows astronomers to study the planet's atmosphere, possible cloud systems, etc., and may also become the successful way for establishing the habitability of an exoplanet.

Directly imaging extrasolar planets requires (a) angular resolution sufficient to spatially

separate the planet from its central star and (b) the means to suppress the diffracted light from the central star such that the planet's brightness becomes comparable to or greater than the residual diffracted star light.

Concerning the first point, at optical wavelengths a conventional telescope of several meters diameter is in principle sufficient to spatially resolve a planet on an orbit comparable to those observed in our solar system, around nearby stars. However, the telescope must be in space or equipped with an extremely efficient ► [adaptive optics](#) system; otherwise, the blurring due to atmospheric turbulences at ground level and at high altitude would degrade too severely the image quality.

As regards the second requirement, this is precisely the role of a coronagraph – to block the starlight as efficiently as possible, using optical elements within the telescope.

The main challenge of using an optical coronagraph for exoplanet imaging is the star-planet brightness contrast ratio. For an Earth-sized planet orbiting a star similar to our Sun, it is about 10^{10} –1 in the visible. Any successful starlight suppression technique must reduce this contrast ratio by a huge factor and must do so at a very small angle, typically equal to $\theta = 2\text{--}5 \lambda/D$, where λ is the wavelength of observation and D is the diameter of the telescope (this value corresponds to the fundamental limit imposed by the phenomenon of ► [diffraction](#)). An important parameter is thus the smallest star-planet angular separation at which this suppression level is achieved to avoid the need for primary mirror diameter larger than, say, 10 m.

There are other challenges albeit a little less stringent.

- The optical bandwidth of the light suppression technique – that is, the range of wavelengths over which the required light suppression can be maintained – should be as large as possible to enable either broadband photometry ($\Delta\lambda/\lambda = 10\%$) or the spectroscopic study of possible exoplanet atmospheric features at various different wavelengths.

- Imperfections in the telescope mirrors and coatings cause *speckles* in the image, that is, small spots of extra light intensity, after the coronagraphic mask; their intensity and variability can easily be high enough to obscure the extremely faint exoplanet image. It is possible to reduce these speckles using deformable mirrors (► [Adaptive Optics](#)), controlled thanks to smart algorithms, or to code them in order to recognize them from the planet image.
- Finally, the weak signal from an extrasolar planet requires substantial integration times (many hours) during which it is essential that the residual stellar leakage be kept extremely stable, which is especially challenging on the ground, considering atmospheric as well as thermal fluctuations. This stresses the need to conduct research of Earth-sized exoplanets from space, but, even then, drifts and vibrations in the telescope cause varying stellar “speckles” that can limit the ultimate sensitivity for planet detection.

Under the pressure of the *planet hunters*, coronagraphy is an area that has shown enormous progress in the past decade as presented below, with a flourishing of very new concepts and technical breakthroughs. Ground-based instruments are already capable of direct detection of exoplanets in the most favorable cases, and a first generation of coronagraphic instruments installed on the largest telescopes (8–10 m diameter) will soon extend by a large factor the population of directly detected exoplanets. It is rather likely that within another decade or so, a coronagraphic space mission will be able to obtain the first images of planets that are analogs to our Earth.

Basic Methodology

A star observed with a perfect telescope in space, thus unaffected by the aberrations of the Earth's atmosphere, will produce an image still surrounded by a halo of light diffracted from the edges of the telescope aperture. Known as the Airy pattern, this halo, which is structured with concentric rings of decreasing intensity (see

Coronagraphy, Fig. 2 The airy pattern is the appearance that the image of a star made by a perfect telescope in space would present. Because of the phenomenon of diffraction, it is not an extremely sharp spot but rather a central core surrounded by characteristic rings. The larger the diameter of the telescope and the smaller the wavelength, the sharper the diameter of the core

Fig. 2), is many orders of magnitude brighter than any extrasolar planet image that would be superimposed on it. Suppressing this halo is the role of a coronagraph.

The Basic Lyot's Coronagraph

The main finding of Bernard Lyot (1939) is that blocking the light with an opaque mask in the focal plane that follows the contour of the bright object (the Sun's surface in his case) is not sufficient at all, because light diffracted by the edge of the mask will spread far beyond the limits of the beam defined by geometric optics and finally will be able to refocus. This is illustrated in Fig. 3 (top and mid panels): the first mask in the focal plane blocks the core of the starlight but leaves residual diffracted light in the reimaged pupil (blue beam). Lyot realized that if a mask with a central circular

Coronagraphy,

Fig. 3 The principle of the Lyot's coronagraph. *Top:* optical scheme of an imaging system with relay optics. The image of a point-like object at infinity (star) is formed by a telescope (a) at its focal plane (b); a lens at this location forms the image of the telescope aperture in another plane (c) where a third lens re-images the star in plane D. The intensity of the light distribution is represented by the curve which is a cut of the image. *Middle:* An opaque mask is put at the focal plane and blocks a large part of the light; however, because of diffraction by the edges of the mask, a fraction of the light is spread beyond the geometrical beam and produces a significant intensity in the focal plane. *Bottom:* a ring mask placed in the pupil plane is efficient to block most of this spurious light

hole slightly smaller than the pupil image was installed, then it would block the essential part of this diffracted light as shown on the bottom panel of Fig. 3.

The New Coronagraphic Concepts

Over the past decade, coronagraphic concepts have proliferated far beyond Lyot's basic vision into a vast family of devices that can be broken down into various broad categories: amplitude or phase-mask coronagraphs, interferometric coronagraphs, and pupil apodization. A fifth family is the external occulter. Each one offers pros and cons that can be measured by a few key parameters. Four of those parameters are especially important:

- The inner working angle (IWA) is the angle of separation from the star below which the flux from the planet is rapidly attenuated and/or beyond which the flux from a resolved star rapidly increases. Currently, the most mature concepts feature an IWA of $\sim 4 \lambda/D$, and it is suggested that an IWA of $\sim 2 \lambda/D$ is achievable.
- The planet throughput, that is, the fraction of the planet's light that reaches the detector. Current throughputs of 8–30% are measured, but claims that a throughput of 80% or higher is reachable are made. In addition, several coronagraphs produce stellar halo suppression within only a fraction of the entire field of view, for instance, a sector or a ring, sometimes referred to as the “discovery space.”
- The sensitivity of the coronagraph to wavefront errors such as image position and focus. These defects arise due to drift and misalignment; even very small ones and their effects can hide or mimic a planetary signature.
- The chromaticity of the coronagraph, that is, its ability to suppress starlight across a broad wavelength range, thus allowing a lower total integration time. Typical useful bandwidth is $\Delta\lambda/\lambda \sim 20\%$ or less.

A thorough study on how each coronagraph design behaves with respect to those key parameters was done by Guyon et al. (2006).

Improvement on the Lyot Concept with Amplitude Masks

Those concepts evolved from Lyot's original solar coronagraph, using a mask at an image of the star, and another mask at a later image of the entrance aperture. It can be shown that, in this basic form, Lyot's concept cannot reach the rejection required for planet detection by several orders of magnitude. An important variant of this concept is the band-limited coronagraph (Kuchner and Traub 2002), where the focal plane mask features a carefully tailored transmission profile confining the residual diffracted light to a well-defined region of the pupil plane. This type of coronagraph has produced excellent laboratory results with a measured contrast of 6×10^{-10} , albeit only in monochromatic light.

Another Lyot variant is the Apodized-Pupil Lyot Coronagraph (APLC), which modifies the entrance pupil with a dedicated transmission mask (Soummer 2004). Laboratory demonstrations to date have achieved contrast levels in the 10^{-6} range. One advantage is that it may be easily adapted to conventional telescopes with central obstruction, such as those used in the next generation of ground-based coronagraph projects.

Phase-Based Lyot Coronagraphs

A similar approach to the Lyot concept is to induce a phase shift rather than an amplitude variation in the focal plane; destructive interference is then produced for on-axis starlight at the pupil level. In the first proposed idea (Roddier and Roddier 1997), the opaque spot of Lyot was simply replaced by a transparent spot of a proper size. The best-known example of this concept remains the four-quadrant phase-mask (4QPM) coronagraph (Rouan et al. 2000), which focuses the starlight onto a mask that shifts light passing through half the focal plane by half a wavelength (see Fig. 4). Such coronagraphs have near-ideal theoretical performance with high throughput and an IWA of $1 \lambda/D$. However, they are also sensitive to star position in the focal plane with respect to the center (angle θ), with performance degrading rapidly with tip/tilt errors. One variant (Rouan et al. 2007) that allows improving on this sensitivity is the 8-quadrant phase mask, where the

Coronagraphy, Fig. 4 Schematics describing the principle of the four-quadrant phase-mask coronagraph and the distribution of the amplitude of the light at the various planes of the optical system

canceling function is proportional to θ^4 rather than θ^2 . There exist several solutions to manufacture them for broadband light: one uses polarization properties of uniaxial crystals, and another is based on the stacking of several 4QPM with rejection performance increasing exponentially with the number of devices. A recently proposed variant of the 4QPM is the optical vortex coronagraph (Foo et al. 2005), which uses a spiral-staircase phase mask. They are more robust against degradation due to the star's position.

Pupil Apodization

Using the Fresnel principle, it can be shown that the diffraction pattern at the focus of a telescope – that is, the actual distribution of intensity in the image of a point source at infinity, such as a star – is directly related to the shape of the entrance aperture. More precisely, this intensity is given by a mathematical transformation of the aperture, called the Fourier transform. The sharp edges of a conventional telescope result in the Fourier ringing that produces the well-known Airy pattern.

Conceptually, the simplest coronagraph would entail a modification of the telescope aperture so it lacks these sharp edges. Called apodization, this modification can be achieved by tapering the telescope transmission through a semitransparent mask that falls gradually to zero transmission at the edges. These masks trade throughput for inner working angle, with a typical mask designed for an IWA of $4 \lambda/D$ having a transmission of 8%. However, manufacturing such a mask with graded attenuation is extremely difficult. Significant effort has been invested in binary approximations to these apodization functions, using sharp-edged metal masks that suppress diffraction over only part of the field of view (Kasdin et al. 2003). Referred to as “shaped pupils,” these masks, which can include micron-sized features, must be carefully fabricated but are feasibly produced with current manufacturing techniques. These designs are inherently achromatic and may be attractive for characterization of planets with known positions, where they can be optimized over a narrow region of the focal

plane. Shaped-pupil masks have been demonstrated in the laboratory at the 2×10^{-9} contrast level, even in broadband light.

An alternative approach to performing apodization is to modify the phase of the light to modulate the intensity in the pupil plane. The phase-induced-amplitude-apodization coronagraph (Guyon 2003) of O. Guyon is based on this approach, using highly aspheric mirrors to redistribute the uniform beam of light into a tapered profile (see Fig. 5). The off-axis planet image is highly distorted, but this effect can be compensated. Contrary to classical apodization, no light collected by the entrance pupil is lost, and the inner working angle can be as small as $2\text{--}3 \lambda/D$ for a throughput of 80% or more. However, this requires optical surfaces very difficult to manufacture, located in various conjugate planes.

Interferometric Coronagraph

The nulling coronagraph is a coronagraph based on a nulling interferometer, as opposed to more familiar designs of an apodized aperture telescope and Lyot coronagraph. This family uses concepts of ► [interferometry](#) and aims at producing destructive interference between two beams. The achromatic interferometric coronagraph (AIC)

was the first of this type to be proposed, by Gay and Rabbia as early as 1997, and has been refined since then (Rabbia et al. 2007). It is basically a Michelson-Fourier interferometer modified by inserting on one arm an achromatic π phase shift and a pupil rotation by 180° (see Fig. 6). The smart idea is to produce the π phase shift by crossing of a focus, thus making it perfectly achromatic. The collimated beam from the telescope is split into two sub-beams forming the two interferometric arms, one where the focus-crossing occurs. The beams are recombined afterward. Other designs have been proposed, such as the nulling coronagraph of M. Shao (2007).

External Occulter Coronagraphs

This type of coronagraph belongs to a peculiar family, since it relies on optical systems separated by several 10, 000 km! In 1960, Lyman Spitzer proposed the combination of a telescope and a starshade in space for discovery of planets. The concept implied enormous distances and starshade dimensions. With recent studies (Cash 2006), the inter-spacecraft separation has been reduced and the level of suppression improved by using petal shapes that would permit operation using a shade with a nominal diameter of 40 m at a

Coronagraphy,

Fig. 5 The principle of the phase-induced-amplitude-apodization coronagraph that produces apodization by modifying the light intensity within the beam

Coronagraphy,

Fig. 6 The principle of the achromatic interferometric coronagraph (AIC) based on destructive interference between two beams, one having suffered the crossing of a focus

telescope-starshade separation of 40,000 km (see Fig. 7). The telescope can be an ordinary space telescope, and its diameter is determined mainly by the requirement to detect faint planets. It has inherently achromatic properties, a strong advantage. However, operation remains the main drawback, since pointing from one star to another requires that the starshade travel several thousand kilometers. To accomplish this within a few weeks demands large starshade velocities and accelerations and thus a substantial power. However, the engineering effort recently done led to some mission scenarios that yield satisfactory efficiency with one occulter and much better with two occulters. The deployment of the large starshade and the propulsion required for many stellar observations remain major technology issues to be addressed.

Future Directions

Wavefront Control

A problem common to all internal coronagraphs is wavefront accuracy and stability. Wavefront errors produced by imperfections in the telescope mirrors and coatings cause speckles in the image after the coronagraph masks have suppressed most of the starlight. The intensity and variability

of these speckles can easily make the faint exoplanet image indiscernible. Achieving Airy ring suppression sufficiently to allow detection of Earth-sized planets would require wavefront phase errors of less than an angstrom (10^{-10} m) – well beyond current polishing capabilities for telescope-sized mirrors. However, the use of a smaller deformable mirror in the optical train allows irregularities in the wavefront to be corrected by feedback, up to a spatial frequency set by the deformable mirror's actuator spacing (Bordé and Traub 2007). With state-of-the-art deformable mirrors, this allows a large fraction of low- and mid-spatial-frequency errors to be removed from the wavefront, producing an image with a characteristic “dark hole” central region (see Fig. 8). It can be shown that with two deformable mirrors, both phase and amplitude defects can be corrected, for an even better improvement.

Calibration of Residual Speckles

The field image is small, a few arcsec in diameter, but an average flux of 10^{-10} times the star flux implies that there could be several hundred speckles as bright as an Earth-like planet. Only one of those speckles is a planet. One technique to identify it makes use of the coherence of starlight, that is, light from the star is coherent (i.e., will interfere coherently) with speckles whose origin is

Coronagraphy, Fig. 7 An artist view of the “New Worlds Imager” project based on a large deployable external occulter at a distance of 40,000 km from a conventional

space telescope. The insert shows a simulated image of the solar system as it would be detected

Coronagraphy, Fig. 8 A deformable mirror with many actuators (*left*) can provide a fair correction of the residual defects in the wavefront, producing an image with a characteristic “dark hole” central region (*right*)

scattered starlight, but will not interfere with light in the focal plane that comes from the planet (or dust) orbiting the star. Because of the interferences, the intensity distribution of the stellar flux features fringes that striate the speckles. The

fringes can be detected by a proper processing, such as a Fourier transform of the image. This is, for instance, the principle of the self-coherent camera proposed by Baudoz et al. (Galicher and Baudoz 2007).

Differential Coronagraphy

Even with the best correction of the wavefront, there will still remain some defects, and it becomes clear that a good way of correcting them is to subtract a similar image that presents the same defects, for instance, of another star or the same star, but where presumably no planet would be present. Several concepts have been proposed in that spirit and several of them have been tested on the sky: spectral differential

imaging, rotational differential imaging, and polarization differential imaging.

In spectral differential imaging (Racine et al. 1999), two images of the star are taken at two close wavelengths, carefully chosen so that the planet would have a different contrast, for instance, within and outside a spectral feature characteristic of some expected compound in its atmosphere (e.g., methane). In another version (Sparks and Ford 2002), one produces the spectra of all the pixels in the image, with a so-called integral field spectrograph, and looks for differences in behavior between speckles, whose size changes with wavelength, and a planetary image whose size is constant, as illustrated in Fig. 9.

Rotational differential imaging (Marois et al. 2006) requires that the telescope be rotated a few degrees around its axis several times, an image being taken at each position: the optical defects will rotate as well, in sky coordinates, while the planet image would remain stable. Figure 10 illustrates this technique.

Finally, in polarization differential imaging, one makes the reasonable guess that the light from the planet is significantly polarized, while the starlight is not: images taken in different polarization states could reveal the planet after subtraction.

Coronagraphy, Fig. 9 Integral field spectroscopy produces spectra of all points in an image: most of the light that remains after coronagraphy is due to speckles whose size changes with wavelength (λ is along the vertical axis), while a planet would be of about a constant size with wavelength

Combining All Techniques

The challenge to beat a contrast of 10^{10} is so difficult that it becomes more and more evident that the good strategy cannot be to rely on one technique alone, but to combine many of them.

Coronagraphy, Fig. 10 Rotational differential imaging. The telescope is rotated around the line of sight and images are taken at each angle. The optical defects that rotate with the telescope can be subtracted

The coming years, or decades, will probably show that the winning instrument, the one that will pick up the first image of a cousin of our Earth, will have included together an efficient coronagraph combining pupil and image plane masks, a super-polished telescope with no central obstruction, one or two deformable mirrors, several differential imaging techniques, and most probably will have been operated in space.

CoRoT 7b

Nader Haghighipour

Institute for Astronomy, University of Hawaii-Manoa, Honolulu, Hawaii, HI, USA

Definition

The exoplanet CoRoT-7b is the seventh planet detected via transit photometry (Fig. 1) by the European space telescope, CoRoT (Léger et al. 2009). With a radius of ~ 1.6 Earth radii (Fig. 2), this planet is the first terrestrial-like planet found outside our solar system. CoRoT-7b revolves around its central star in a very short-period orbit

CoRoT 7b, Fig. 1 Light curve of CoRoT-7 showing 153 transits of CoRoT-7b

CoRoT 7b, Fig. 2 CoRoT-7b in comparison to the solar system planets

of 20 h making this planet one of the few with extremely small orbital periods. The close proximity of this planet to its Sun-like host star (which is about 500 light-years away) implies that it must experience extreme conditions. For instance, its surface may be covered by lava or boiling oceans (Fig. 3). A total of two planets were detected in the system, and the companion CoRoT-7c has a period of 3.7 days (Queloz et al. 2009).

Since the discovery of CoRoT-7b, many attempts have been made to determine the mass of this planet using radial velocity data (Léger et al. 2009; Queloz et al. 2009; Hatzes et al. 2010, 2011; Boisse et al. 2011; Ferraz-Mello et al. 2011). However, due to stellar activities, the value of the mass of this planet is uncertain. The current estimates, using a model for stellar activity, put the mass of this planet around 4.7 Earth masses (See Haywood et al. 2014; Dai et al. 2019).

Discovery of CoRoT-7b opened a new field in the studies of extrasolar planets. The mass of this planet puts this object in the category of rocky super-Earths (e.g., Haywood et al. 2014). The latter motivated many researchers to develop models for the interior and composition of super-Earth planets.

Being so close to its host star, CoRoT-7b may not have significant atmosphere. Because this planet is in a tidally locked position with its parent star, which causes one side of it to face the star at all time. It is believed that the surface of its bright side must have been depleted of volatiles, suggesting that the atmosphere of the planet may be rich with rocky vapors.

Definition

The CoRoT mission is a satellite for the study of the stellar structure through asteroseismology and for the detection of transiting exoplanets.

Overview

CoRoT (for Convection, Rotation, and Planetary Transits) is the first space mission designed for the study of the stellar physics through ► [asteroseismology](#) and for the search for exoplanets with the method of transits. It was launched on December 27, 2006, from Baïkonour, and sent scientific data up to November 2012. CoRoT was developed and operated by the French space agency ► [CNES](#) and French CNRS laboratories LESIA, LAM, IAS, and IRAP, with significant contributions from Austria, Belgium, Brazil, ESA, Germany, and Spain.

Basic Methodology

Stars, acted on by gravity, pressure, and Coriolis forces, behave as oscillators with many specific

modes. These oscillations are detectable through tiny variations in the stellar luminosity, and their analysis provides important parameters on the stars' internal structure.

When an exoplanet travels between its host star and us, it induces a weak drop of the star's luminosity (a mini-eclipse). The detection of this periodic ► [transit](#) in the star's light curve, together with its careful analysis, reveals the existence of the exoplanet and provides important characteristics such as its radius, its orbit parameters, and the rotation period of the star.

CoRoT's wide field of view enables it to monitor the flux from thousands of stars for uninterrupted period of several months, in order to detect and measure the tiny variations in this flux, either for stellar activity measurements or for exoplanets' transit detection. The satellite carries a 27 cm, two mirrors off-axis visible telescope focusing the stars' light on a focal unit hosting the four (1) frame transfer CCD matrices of $2,048 \times 4,096$ pixels (Baglin et al. [2007](#); Auvergne et al. [2009](#)). The detectors, whose temperature is regulated at -40°C , have a high quantum efficiency in the visible wavelengths. On top of this instrument, a baffle reduces the parasitic stray light down to a few photons/s/per pixel (Fig. 1).

1. From March 2009, only two CCD matrices were left operating.

Key Research Findings

Asteroseismology

One hundred fifty-six various bright stars and 35,000 red giants were observed for uninterrupted durations of about 80–150 days in most cases. A few highlights of the results already achieved by CoRoT are presented here.

Solar-Like Pulsation, Granulation, and Convective Core

CoRoT measured solar-like oscillations and granulation in stars hotter than the Sun (Michel et al. [2008](#)). The modes' widths (inversely proportional to the lifetime of the modes) have been found to be noticeably larger than those in the Sun and larger

than expected. In terms of stellar structure, the first seismic interpretations of the measured eigenfrequencies address the crucial question of the extension of the mixing beyond the stellar convective core. This key process is responsible for

the present large uncertainty on stellar age determinations.

Red Giants and the Future of Our Sun

Toward the end of their lives, stars like the Sun expand and become ► [red giant](#) stars. Because of the turbulent convection in their outer layers, red giant stars are expected to exhibit solar-like oscillations, but in a much lower range of frequencies (10–100 μHz). CoRoT data allowed to measure clearly for the first time such oscillations in a large sample of red giants (Fig. 2).

In addition, unambiguous evidence of the excitation of both radial and nonradial modes was provided, previously an open question. CoRoT data also confirmed the existence of modes with lifetimes of the order of one month (De Ridder et al. 2009; Carrier et al. 2010).

The first theoretical modeling of this stellar evolution stage suggests that it would be possible to explain the observed oscillation spectra and their variety for different stages of the structure of stars along their expansion in the red giant phase. Indeed these red giants of different masses and ages are representative of all the successive generations of stars in the Galaxy. Through the asteroseismology of red giants, CoRoT therefore opened the door for a new method for galactic archeology.

New Type of Pulsators

CoRoT data led to the discovery of new types of pulsating stars. HD180872 is one of them. This

CoRoT Satellite, Fig. 1 The CoRoT satellite during its integration onto the Soyuz launcher

CoRoT Satellite, Fig. 2 Power spectrum of the CoRoT observations of the red giant HR 7349 (Carrier et al. (2010). Reproduced with permission © ESO)

star was known to belong to the Beta Cephei class of pulsators, young massive stars which are progenitors of SN-II type supernovae and thus mainly responsible for the enrichment of the universe in carbon and oxygen. These stars classically show oscillation periods of the order of a few hours. In the lightcurve of HD180872, CoRoT data revealed, at very low amplitude, the existence of higher-frequency modes, due to stochastic oscillation, very comparable to the ones observed in the Sun (Belkacem et al. 2009). This confirms the existence of a powerful convective zone and will allow the scaling of its energy. This discovery opens new perspectives in the study of these objects where low-frequency oscillations and high-frequency ones could be used in a complementary way to probe the center and the outer layers of the star.

Search for Exoplanets

One hundred sixty three thousand six hundred eighty two stars were monitored by CoRoT for duration up to 6 months. Thirty-five companions (mainly exoplanets and a few brown dwarves) have been confirmed so far, and 130 candidates identified (Fig. 3).

These discoveries widen the variety of the known exoplanets family (Table 1). CoRoT-3b, the heaviest and the densest one, lies at the frontier with ► [brown dwarfs](#) (Deleuil et al. 2008). On the opposite side, CoRoT-7b is the first telluric exoplanet which mass and radius are known (Léger et al. 2009; Queloz et al. 2009). It provides

evidence for the existence of Earth cousins in orbit around Sun-like stars. Several planets such as CoRoT-1b, CoRoT-2b, CoRoT-11b, and CoRoT-20b challenge the current theory for planet formation and/or migration in a disk.

CoRoT-7b is phase-locked, that is to say that its orbital and rotational periods are equal (0.85 day). Therefore, it shows always the same face to its star (as the Moon does relatively to the Earth). This induces a very hot temperature (up to 2,600 K) on the dayside and a very cold one (down to 50 K) on the nightside.

CoRoT-9b is the first transiting temperate exoplanet. Indeed, the medium surface temperature of this Jupiter-like gaseous planet stands between -20°C and 150°C , depending on the models, and the temperature excursion between daytime and nighttime is probably low (Deeg et al. 2010). Its low eccentricity ensures a relatively low seasonal temperature variation. Further spectroscopic observations of its transits should open a new era in the study of exoplanets, allowing planetologists and biochemists to enter the game.

CoRoT also detected the secondary transit of exoplanets at the visible wavelength for the first time (Alonso et al. 2009a, b). This phenomenon occurs when the planet disappears behind its star, inducing a slight dip in the total flux received from the two of them. In the case of CoRoT-1b, for instance, this dip was only of 2/10,000. This allowed to measure the planet albedo (reflectivity), which turns to be of about 10% (compared to about 40% for the Earth).

CoRoT Satellite,

CoRoT Satellite, Table 1 Characteristics of a sample of CoRoT planets

Name	Period (day)	Mass (M_{Jupiter})	Radius (R_{Jupiter})	Mean density (g/cm^3)	Star type	Main features
CoRoT-1b	1.51	1.03	1.49	0.38	G0V	Metal poor host star – secondary transit detected
CoRoT-2b	1.74	3.31	1.46	1.31	G7V	Very young star (~0.5 billion years), challenges planet formation theory – secondary transit detected
CoRoT-3b	4.26	21.6	1.0	26.4	F3V	Brown dwarf or super planet
CoRoT-5b	4.03	0.46	1.39	0.217	F9V	Very low density
CoRoT-7						
b	0.85	0.025	0.157	7.50	G9V	CoRoT-7b first telluric exoplanet ($M = 5.4 M_{\text{Earth}}$, $R = 1.6 R_{\text{Earth}}$)
c	3.7	0.043	NA	NA		
d	9	NA	NA	NA		
CoRoT-9b	95.27	0.84	1.05	0.90	G3V	First moderate temperature transiting exoplanet
CoRoT-10b	13.24	2.75	0.97	3.7	K1V	High eccentricity (0.53)
CoRoT-11b	2.99	2.33	1.43	0.99	F6V	Fast-rotating star (period < 2 days)
CoRoT-14b	1.51	7.6	1.09	7.3	F9V	Very dense hot giant
CoRoT-15b	3.06	63.3	1.12	96	F7V	Very dense brown dwarf
CoRoT-20b	9.24	4.24	0.84	8.9	G2V	Very young system (100 million years). A very dense planet challenging planet formation theories. High eccentricity (0.56)

In addition to transits, CoRoT detected a number of other effects and demonstrated how they could be used to better characterize the star-planet systems, such as the Rossiter-McLaughlin effect and the ellipsoidal and beaming effects (detected for the first time for a substellar companion with CoRoT-3b).

Applications

CoRoT will let us make a giant step forward in our knowledge of stars' and the planets' birth, life, and death and therefore bring a major contribution of our knowledge of the Universe we live in. It also paves the way for the search for life in the universe: on one hand, it identifies planets for which detailed analysis with other techniques will be of particularly high interest. On the other hand, it eased the work of its successors, the US mission ► [Kepler](#) (Basri et al. 2005) and the future European mission ► [Plato](#) (Catala et al. 2010), by providing a great know-how on the transit

method, in particular on the optimal strategy for targets selection, for data processing, and on-the-ground follow-up. It also helps the delicate thinking of the astronomical community in the definition of the best strategy for the search for extraterrestrial life.

Future Directions

In stellar physics, CoRoT was a pioneer in establishing the richness of asteroseismology. The future will probably be devoted to the increase of the sample and of the variety of stars observed. CoRoT, Kepler, and later on Plato will be major contributors; ground surveys might also contribute, especially for low-frequency oscillations.

Several international scientific bodies were set up to propose a roadmap for the exoplanets and extraterrestrial life detection, in Europe (EP-RAT, Blue Dots initiative) or in the USA (Decadal Survey). The Pathways Conference in

Barcelona in September 2009 proposed a three-step strategy:

1. Statistical study of planetary objects
2. Designate sources suitable for spectroscopic follow-up
3. Carry out spectroscopic characterization

The first and second steps would involve several methods such as transits, radial velocities, astrometry, and microlensing. The Kepler mission and, on a larger scale, the Plato mission intend to make a wide census and characterization of transiting planetary systems. TESS, CHEOPS, GAIA, Euclid, and ground surveys will also contribute. The spectroscopic characterization will require large ground telescopes, such as the ESO VLT and the future large telescopes (E-ELT, TMT), and space-based facilities such as the James Webb Space Telescope.

Corotation Torque

Sean N. Raymond
Laboratoire d'Astrophysique de Bordeaux,
CNRS, Université de Bordeaux, Bordeaux,
France

Definition

The corotation torque is that exerted on a planet's orbit by material (usually gas) co-orbiting with the planet. This has a very important effect on the orbital migration of planets of less than roughly 50 Earth masses that form in gaseous ► [protoplanetary disks](#). Recent analysis suggests that very rapid, inward “type 1” migration – caused by tidal interaction between the disk and a planet – may in fact be slowed or even reversed in certain situations due to the corotation torque.

History

In 1965, two American physicists, Arno Penzias and Robert Wilson, accidentally discovered electromagnetic background noise at 7.35 cm wavelength in the millimeter radio wave region. Penzias and Wilson were working for the Bell Telephone Laboratories on satellite communication improvement when they brought to light this homogeneous and isotropic radiation resulting from the universe as its whole; it was quickly read as fossil radiation from a universe that was originally dense and hot and had cooled off because of its expansion to a 3.5 K temperature today. In 1978, Penzias and Wilson got the Nobel Prize for this discovery.

However, there had been some previous investigations in this general area. The French physicist Charles-Edouard Guillaume had calculated in 1896, by Abney's works and according to the black body's law that Stefan granted in 1879, that an isolated body in the space, only subdued to stars' radiation, would see its temperature increasing of nearly 5 K. In 1926, Sir Arthur Eddington shows that the real temperature of the space, due to star's radiance, is 3.18 K. But there was a lack of theoretical framework to give sense to theoretical calculations assuming some model of the universe. Indeed, Edwin Hubble proved in 1924, with detailed observations, that the universe is formed of myriads of galaxies. In 1929, he also discovered empirically that these galaxies all move away from one another. At the same time, the works of the Belgian physicist Georges Lemaître interpreted the observational data in terms of relativity theory to show that the universe is expanding.

In the 1940s, the American astrophysicist George Gamow laid down the basis of nucleosynthesis, the formation of the chemical elements. According to Gamow, the chemical

elements could have been made at a hot and dense period of the universe, in the bosom of an “original soup” that he named “ylem” and that represented an early stage of the Big Bang. In 1948, two Gamow’s collaborators, Alpher and Herman, developed Gamow’s ideas and predicted the existence of a diffuse radiation background with a 5 K temperature. Within this theoretical framework, this cosmic background radiation has become the experimental mainstay of the Big Bang theory, which includes the universal expansion and the nucleosynthesis of the lightest elements. The background radiation has recently been measured very accurately in 2001 and 2006, respectively, with satellites COBE and WMAP.

Cosmic Ray, Ionization Rate

Steven B. Charnley

Solar System Exploration Division, Code 691, Astrochemistry Laboratory, NASA Goddard Space Flight Center, Greenbelt, MD, USA

Definition

The cosmic ray ionization rate in the ► [interstellar medium](#) is the rate at which H₂ molecules as well as atomic H and He are ionized by the flux of galactic cosmic rays. This process is fundamental to driving the chemistry in dense interstellar clouds. Current estimates place the value in the range $1\text{--}40 \times 10^{-17} \text{ s}^{-1}$ with the higher values being more appropriate for lower-density diffuse interstellar clouds.

Cosmic Rays

Nikos Prantzos¹ and Jun-Ichi Takahashi²

¹Institut d’Astrophysique de Paris, Paris, France

²Yokohama National University, Faculty of Engineering, Yokohama, Japan

Keywords

Cosmic rays · Electrons · Energetic particles · Nuclei

Definition

Galactic cosmic rays are high-energy (relativistic) electrons and nuclei, accelerated by supernova explosions and massive stellar winds and

traveling through the Galaxy by scattering on fluctuations of interstellar magnetic fields, which render their flux isotropic.

Overview

The energy spectrum of galactic cosmic rays (CR) covers the energy range from a few MeV/nucleon up to 10^{15} MeV/nucleon and is well approximated by a power-law $N(E) \propto E^{-\alpha}$ of slope $\alpha = -2.7$ below 10^6 GeV/nucleon and $\alpha = -3$ above that. Below a few GeV/nucleon, the CR spectrum progressively flattens (with α even becoming positive) and its intensity varies, in a way that anticorrelates with solar activity ("solar modulation"); the solar wind prevents the lowest energy CR from entering the heliosphere. The total galactic power of CR is estimated to be 10^{41} erg/s, that is, about 10 % of the total kinetic power of [supernovae](#) and stellar winds, which are thought to be the main CR accelerators. However, no galactic accelerator can account for the highest energy CR (up to $\sim 10^{12}$ GeV), the origin of which remains unknown. The residence time of CR in the galactic disk is $\sim 10^7$ years. The composition of CR nuclei is overall similar to the solar one: it consists of ~ 87 % protons, 12 % alpha nuclei (helium atoms), and 1 % heavier nuclei (in addition to the nucleonic component ~ 3 % of the CR flux are high-energy electrons). The major uncertainties are at extremely high energies and for elements heavier than iron. There are several important differences: the metallicity (see [► Metallicity](#)) of CR is ~ 10 times solar, with refractory elements (Fe-peak nuclei) relatively more enhanced than the volatiles; and the fragile Li, Be, and B nuclei are 10^6 times more abundant in CR than in the Sun. These features suggest that CR are accelerated from a mixture of interstellar gas and dust grains (where refractory elements are overabundant), and during their propagation in the Galaxy, they spallate abundant CNO nuclei to produce Li, Be, and B.

From the standpoint of astrobiology, CR may play a crucial role, either as effective energy sources for synthesizing the precursors of

terrestrial bioorganic compounds in interstellar media or as agents inducing mutations in living organisms and thereby promoting biological evolution. They may even be lethal in case of a nearby supernova.

Cosmic Rays in the Heliosphere

Don F. Smart
Air Force Research Laboratory (Emeritus),
Bedford, MA, USA

Keywords

Cosmic radiation · Solar modulation

Definition

Cosmic rays are very energetic particles thought to pervade space. Within the solar system, the cosmic ray flux is modulated by the solar activity cycle.

Overview

Cosmic radiation observed at the Earth consists of ~83% protons, 12% alpha particles, 1% heavy nuclei with atomic number >2, and ~3% electrons. The cosmic ray composition of the most common elements has been measured to a reasonable precision (see Fig. 1). The major uncertainties are at extremely high energies and for elements heavier than iron. The local interstellar spectrum (outside the heliosphere) is constant, but inside the heliosphere, the spectrum and fluence of particles below ~10 GeV/nucleon are modified by solar activity with a phase that is the inverse of the solar sunspot cycle. The cosmic ray flux decreases with increasing energy and the proton flux is reduced by 50% at 1.5 GeV. The cosmic ray flux of the heavier nuclei is reduced by 50% at 0.9 GeV/nucleon. The maximum total isotropic flux in free space at 1 AU is ~3 particles cm⁻² s⁻¹ during solar minimum conditions; during solar maximum conditions, the total cosmic ray flux is

reduced by ~40%. The diffusion of the cosmic ray flux inwards through the turbulent interplanetary medium results in an average radial cosmic ray gradient of a few percent per AU. The cosmic radiation flux at Mars (1.5 AU) is only a few percent larger than at Earth.

The major factors modulating the cosmic radiation intensity include the solar wind speed, turbulence in the solar wind, and solar magnetic polarity. Cosmic ray modulation theory adequately models the flux at the Earth and at our most distant space probes. The modulation parameter, designated by the symbol ϕ , is normally expressed in units called MV. The modulation parameter at 1 AU during solar minimum typically ranges between 400 and 500 MV; however, extreme solar activity can generate transient modulation levels in excess of 1,600 MV (see Fig. 2).

The particle flux below ~2 GeV/nucleon makes the most important contribution to radiation dose. Since the energy deposition in matter is proportional to the square of the atomic charge,

Cosmic Rays in the Heliosphere, Fig. 1 A model of the modulated differential cosmic ray spectrum at 1 AU for the most abundant elements in the cosmic ray flux during

Spherule comes from the Greek word “sphaira” for sphere. Cosmic spherules are solid, rounded particles ranging from micrometer to millimeter in size with distinct chemical compositions indicating

Cosmic-Ray-Induced Desorption

Eric Herbst
 University of Virginia, Charlottesville, VA, USA

Definition

Cosmic rays, high-energy nuclei, travel throughout the universe at nearly the speed of light and bombard both gas-phase molecules and dust particles in interstellar space. The bombardment of dust

particles leads both to sputtering of material and to the heating up of the particles. The heating in turn allows molecules to “evaporate” into the gas, a term more accurately known as “desorption.”

Overview

Cosmic rays are high-energy (MeV–GeV) particles, mainly protons but including a range of heavier atomic ions such as metals, likely formed in supernova explosions. When these particles enter an interstellar cloud, they interact with both the gas, producing gaseous ions, excited neutrals, and photons, and dust particles, with and without ice mantles. The interactions between cosmic rays and atoms and molecules in and on the grain can be divided into elastic collisions (with nuclei) and inelastic collisions (with electrons). Cosmic rays of heavy elements can play an important role in these collisions. The elastic collisions can be regarded as ballistic events, which can blow material off of the grains via a process known as “sputtering,” in which backward scattering of the target material occurs. The inelastic collisions with electrons can be partially converted into heat, which raises the temperature of a whole grain to a maximum temperature, depending upon the size and heat capacity of the grain, before cooling ensues. At the standard initial grain temperature of 10–20 K, only very weakly bound species can desorb within a physically reasonable lifetime, but higher temperatures lead to a dramatic enhancement in thermal desorption, especially from outer layers of ice mantles found in cold clouds (Hasegawa and Herbst 1993). The enhancement of the rate coefficient for thermal desorption is clearly shown by the equation

$$k_d = \nu \exp(-E_d/kT),$$

where ν is the so-called trial frequency for physisorbed adsorbates ($\approx 10^{11} - 10^{12} \text{ s}^{-1}$) and E_d is the energy needed for thermal desorption. With a desorption energy for physisorbed species of 1000 K ($\approx 0.1 \text{ eV}$), the rate coefficient for desorption increases from 10^{-31} s^{-1} at 10 K to 10^6 s^{-1} at 70 K, a maximum temperature estimated for grains of size 0.1μ with the low cosmic-ray flux

present inside dense interstellar clouds. Recent observations indicate that the cosmic-ray flux can be up to two orders of magnitude greater in lower-density clouds or on the edges of dense clouds, with special enhancement in lower-energy cosmic rays, which possess high cross sections for inelastic collisions. The net result in such sources is an increase in the rate of cosmic ray induced heating events by up to two orders of magnitude. A new estimate for the size of the enhancement in dense clouds is at least one order of magnitude (Kalvans 2016). In addition, it should be noted that much of the surface area for grain populations occurs at smaller sizes than 0.1μ , and these smaller grains will rise to still higher temperatures. Other desorption mechanisms caused by cosmic rays include spot heating, and ejection of ice fragments, although there is still little evidence for grain explosions, which would require large populations of radicals.

Meteoritics

Definition

Cosmochemistry is the study of the formation and evolution of the Solar System and its individual components through the analysis of extraterrestrial samples in the laboratory.

History

The first mention of a meteorite in western literature concerns the prediction of the fall of a meteorite by Anaxagoras of Clazomenae in the year 467 BC. During Antiquity, ► [meteorites](#) were revered as gods in many places of the Mediterranean basin. During the Middle Ages, they were still considered with superstition and fear. Though more rational interest was paid to meteorites in the Renaissance, they still belonged to the reign of natural wonders. Interestingly, the Enlightenment era failed to identify the true provenance of meteorites, probably because analytical chemistry was yet to be developed.

Ernst Florens Chladni (1756–1827) can be seen as the founder of cosmochemistry. At a time when most scientists believed meteorites were mere stones from volcanoes or atmospheric condensations, he proposed in a provocative pamphlet published in 1794 that meteorites were extraterrestrial objects. This bold proposition was harshly discussed for the next 10 years among the European scientific community. It was finally accepted in 1803 after the fall of a meteorite at L'Aigle in France and the publication of a detailed report by Jean-Baptiste Biot (1774–1862, Fig. 1). Being the first scientist to travel to the place of a meteorite fall and helped by a beautiful literary style, Biot was able to convince his peers that stones fell from the sky.

At that time, many of the early cosmochemists such as Chladni, Laplace (1749–1827), or Biot thought meteorites came from the Moon. It is not until the mid-nineteenth century that scientists

Cosmochemistry, Fig. 1 Jean-Baptiste Biot (1774–1862). After the fall of the L'Aigle meteorite in 1803 in France, he wrote a report which definitely established the extraterrestrial origin of meteorites

realized that most meteorites come from ► [asteroids](#), the first of which, Ceres, was discovered in 1801. After the recognition of the extraterrestrial nature of meteorites, the field of cosmochemistry blossomed. It started with the development of elaborate classification schemes (strikingly similar to the one used now) and chemical analyses, which expanded on the pioneering studies of Lavoisier (1743–1794) and Howard (1774–1816). The identification of new minerals and of chondrules, a major component of the primitive meteorites unknown in terrestrial rocks, clearly set meteorites apart from terrestrial rocks.

Basic Methodology

Meteorites are studied using the same techniques as terrestrial rocks. The petrography (relative

abundance and textural relationships between the different components and individual minerals) and mineralogy (structure and chemical composition of minerals) are made on rock sections (i.e., cut and polished) with a diversity of optical and electronic microscopes. Isotopic analyses are performed with a diversity of mass spectrometers. Secondary ion mass spectrometers and thermo ionization and inductively coupled plasma mass spectrometers are used for a wide range of rock-forming elements. While the former provide a very good spatial resolution (micron scale), the latter have reached precisions of the order of tens of ppm. Organic matter within meteorites is now studied in detail with techniques imported from the oil industry (► [Meteorite, Murchison](#)).

Key Research Findings

Today, extraterrestrial samples can be collected directly from space thanks to sophisticated and expensive space missions, such as Stardust, which brought back cometary dust from the Wild 2 comet in January 2006. But these missions are still rare. Most cosmochemists focus their work on meteorites and micrometeorites that fall on Earth, a cheaper way to sample celestial bodies millions of kilometers away. Roughly 50 t of meteorites (size range 1 g–100 kg) and 7000 t of micrometeorites (<mg) fall on the Earth's surface every year. In April 2010, the number of meteorites registered by the Meteoritical Society was 38,800.

Nowadays, cosmochemistry is a very active scientific discipline, which greatly benefits from its proximity with other fields, especially astrophysics, but also geology and material sciences. Thanks to the diversity of extraterrestrial samples (meteorites as well as lunar rocks and cometary dust brought back by space missions) and to the wealth of techniques used and its fecund interaction with a large number of neighboring fields, it can address a diversity of fundamental scientific questions. The following point of view on cosmochemistry is complementary to that presented in the entry ► [meteorites](#); special emphasis will be given to important discoveries and open questions.

What Do Meteorites Look Like?

Meteorites are rocks made of minerals (and occasionally glasses). They can be distinguished from terrestrial rocks mainly by their fusion crust (► [Meteorite, Allende](#)), i.e., a mm-thick veneer of glass produced during their entry at cosmic velocity (~10–20 km/s) into the Earth's atmosphere.

Though meteorites can be divided into 135 different classes, mineralogically there exist three main groups of meteorites (Fig. 2): stones (94% of the observed falls), stony irons (1%), and irons (5%). Though some of them might have an impact origin, irons are believed to represent the cores of large, differentiated asteroids or planetesimals; and stony-iron meteorites are thought to be mixtures of core and mantle or core and crust material. Stony meteorites can be divided into chondrites and achondrites. The former are characterized by a large abundance of small mm-sized blobs known as chondrules (see below) that have a chemical composition similar to that of the Sun. Achondrites are magmatic rocks. They lack chondrules and have a strongly fractionated chemical composition relative to that of the Sun; they are believed to originate from the crust of planets and other smaller differentiated bodies.

Chondrites are made of calcium-aluminum-rich inclusions (CAIs), chondrules, and matrix (Fig. 3). The relative abundance of these three components varies between chondrite groups. In most chondrites (except CIs), chondrules represent the dominant component. CAIs are an assemblage of calcium and aluminum oxides and silicates (► [CAIs](#)). Some of them show evidence of melting. Chondrules are an assemblage of iron-magnesium silicates plus metal and sulfides. Chondrules usually show an igneous texture indicating they were at some point extensively melted in the solar protoplanetary disk. Matrix is made of fine-grained (<1 μm) iron-magnesium silicates, metal, and sulfides. In the case of carbonaceous chondrites, the matrix is rich in organic matter. For most chondrite groups, the matrix has been modified on the parent asteroid due to secondary geological processes such as thermal metamorphism or hydrothermal alteration.

Cosmochemistry,

Fig. 2 Simplified classification of meteorites. *Gray boxes* indicate differentiated meteorites, while *white boxes* indicate primitive meteorites. Primitive achondrites (shaded gray) are objects having the composition of chondrites and the texture of differentiated rocks

Achondrites, at first sight, look like terrestrial igneous rocks. They are made of mafic minerals such as olivine and pyroxene and an aluminum-rich silicate, plagioclase. If it were not for the

fusion crust, they would be difficult to distinguish from terrestrial basalts, though detailed studies show they come from evolved bodies, which had a different geologic history than the Earth.

Cosmochemistry,

Fig. 3 Chemical composition of the chondrite GRO 03116. Red, green, blue, yellow, and white code, respectively, for iron, magnesium, silicon, calcium, and aluminum. One can appreciate the richness in reduced iron (red), the high abundance of chondrules (green-blue iron-magnesium silicate spheres), and the rarity of CAIs (in yellow white). (Picture courtesy of Anton Kearsley (NHM))

**Where Do Meteorites Come From?**

Most meteorites are chondrites. They are cosmic sediments whose components were made in the protoplanetary disk and cemented together via poorly characterized processes. Chondrites were not differentiated, i.e., metal and silicates were not segregated after melting. The larger a body is, the easier it is to melt; therefore, the undifferentiated nature of chondrites indicates they originate from small celestial bodies, ► [asteroids](#) or ► [comets](#). The determination of the orbits of a few meteorites has confirmed that most chondrites come from asteroids, though some, such as CI chondrites, could come from comets (► [Meteorite, Orgueil](#)). It is however not possible to pinpoint from which specific asteroid meteorites come from, except for one noticeable exception. The good match between the infrared spectrum of HED meteorites and the asteroid (4) Vesta suggests these meteorites come from that asteroid.

On the other hand, the compositional and mineralogical similarities of roughly 100 meteorites to lunar samples collected by the space missions Apollo and Luna establish that they come from the Moon. The same number of meteorites – forming the SNC (Shergottite-Nakhilite-Chassignite) group – come most likely from the planet Mars. This was demonstrated by the excellent match in

Cosmochemistry, Fig. 4 Chemical composition of the gas trapped in the SNC (Martian) meteorite EET 79001 compared to that of the Martian atmosphere determined by the Viking spacecraft in the 1970s. (From Bogard et al. (1984))

composition between gas bubbles trapped within meteorites from the SNC group and the Martian atmosphere composition measured by the Viking landers in 1976 (Fig. 4).

The origin of micrometeorites is still debated. Recent work suggests they come mostly from comets rather than from primitive asteroids. It is worth noticing that the precise origin of

micrometeorites does not matter much, as the analysis of cometary samples returned by the Stardust mission has demonstrated that comets and primitive carbonaceous asteroids are similar in nature.

Dating Meteorites and Other Bodies: A Rough Sequence of Events

One of the major achievements of cosmochemistry has been to date extraterrestrial samples. In 1956, Claire Patterson proposed an age of 4.55 Ga for the Solar System and the Earth (see ► [Earth, Age of](#)). To accomplish this fundamental task, he used two long-lived radionuclides ^{235}U and ^{238}U which decay into ^{207}Pb and ^{206}Pb , with respective half-lives of 0.7 and 4.5 Ga. The long-lived radioisotope ^{87}Sr ($T_{1/2} = 48$ Ga) was also extensively used to date early Solar System processes during the 1960s and 1970s, but is today too imprecise for the task (compared to other systems). Iodine-129 with half-life of 15.7 Ma was the first short-lived radionuclide whose past presence in a meteorite was unambiguously demonstrated. Many more were to follow (see below).

The use of chronometers, combined with astronomical observations, made it possible to date the sequence of events from the collapse of the portion of a molecular cloud to the Solar System in its present configuration. The lifetime of the molecular cloud precursor of our Solar System is not known, but molecular clouds usually live for a few million years before they get disrupted by the harsh effects (photoionization, powerful winds) of the stars to which they gave birth. The following stage, i.e., the gravitational collapse of a portion of the molecular cloud, takes some 100,000 years and can be seen as a transition phase during which, however, important gas-grain chemistry occurs. In the next stage, the protosun is surrounded by an accretion disk through which it is fed with matter. Because it is within the same disk that the components of chondrites, chondrites themselves, planetesimals (from 1 km up to 1000 km), and large planetary embryos (1000 km-sized bodies) are formed, the accretion disk or solar nebula is also called a protoplanetary disk.

CAIs most likely formed first in the protoplanetary disk 4568 Ga ago, followed by chondrules which formed 1.5 Ma later. The accretion of chondrites from their components and of planetesimals from chondrites occurred as soon as chondrules were formed. The disk was dissipated after a few million years, according to astronomical observations of other stellar systems. Embryos probably grew on that same million-year timescale.

Chemical and Isotopic Composition

CI chondrites have the same chemical composition as the Sun for all elements except for the most volatile ones, such as H, He, C, and N (Fig. 5). This discovery suggests that chondrites are extremely primitive rocks that sample the earliest phases of the protoplanetary disk. The relatively small chemical fractionation of other chondrites relative to CI chondrites is attributed to physical processing in the protoplanetary disk, either before or during chondrule formation.

The bulk isotopic and chemical composition of chondrites is the result of the chemical evolution of the Galaxy over the last 10 billion years. Interestingly enough, the isotopic composition of all but a few elements in Solar System bodies (chondrites, achondrites, Earth, Mars, etc.) is remarkably identical in meteoritic, lunar, and terrestrial samples. This indicates that Solar System matter was well homogenized by high-

Cosmochemistry, Fig. 5 Chemical composition of the Sun's photosphere compared to that of the CI chondrites (shown on a logarithmic scale, normalized to silicon)

temperature processes in the protoplanetary disk, possibly linked to chondrule formation.

A few solids escaped this processing and preserved their chemical and isotopic properties. These are called presolar grains. They were discovered in the matrix of chondrites in the late 1980s at the University of Chicago. They were isolated thanks to severe chemical treatments and recognized because of their isotopic composition, radically different from that of Solar System matter. Presolar grains were made in the atmospheres of stars formed hundreds of millions before our Solar System. Thanks to their study, stellar nucleosynthesis has become an experimental field.

The oxygen isotopic composition of meteoritic components, e.g., CAIs and chondrules, is an exception to the similarity discussed above, in that it varies a great deal. While chondrules have a composition roughly similar to that of the Earth, CAIs are enriched in ^{16}O by at least 4% relative to chondrules. The origin of that enrichment – known since 1973 – is not well understood. The most popular model – the self-shielding model – invokes photochemical processes either in the parent molecular cloud or in the protoplanetary disk (► [Oxygen Isotopes](#)).

Short-Lived Radionuclides

Short-lived radioisotopes (SRs) are radioactive elements with half-lives ranging from a few weeks to 100 Ma. Their presence in the nascent Solar System is inferred from excesses of their daughter isotopes in meteoritic components, mostly in primitive components such as the CAIs. Some SRs were present in the protoplanetary disk at abundances significantly higher than the expected average contribution of the interstellar medium. These SRs therefore require a last-minute origin. They were either made within a star such as a supernova and injected into the nascent protoplanetary disk or produced within the disk itself via nuclear reactions between solar cosmic rays and ambient dust. The origin of SRs is a hotly debated topic of cosmochemistry, as it has important consequences for our understanding of: (1) the early Solar System chronology, (2) planetesimal heating, and (3) the astrophysical context of our Solar System birth.

If SRs were homogeneously distributed in the Solar System, they can be used to define a chronology of Solar System events. Aluminum-26 ($T_{1/2} = 0.74$ Ma), ^{53}Mn ($T_{1/2} = 3.7$ Ma), and ^{182}Hf ($T_{1/2} = 9.0$ Ma) are especially useful as chronometers because their initial content is known in a diversity of objects. Ages based on SRs confirm the early formation of CAIs relative to chondrules and the rapid evolution of Solar System bodies. Dating of some iron meteorites indicate indeed that differentiation of large planetesimals or asteroids occurred contemporaneously with CAI formation.

Aluminum-26 and ^{60}Fe ($T_{1/2} = 2.6$ Ma) emit gamma rays when they decay. They have been proposed as heat sources for planetesimals. The extent of heating and therefore the subsequent geological evolution depends on the initial content of these two SRs in the parent-body considered – and therefore on their initial content in the Solar System – as well as on the timing of formation of the bodies considered. Current models indicate that ^{26}Al is a more efficient heat source than ^{60}Fe .

The presence of ^{60}Fe in the Solar System seems to indicate that the Sun was born in a second-generation molecular cloud enriched in radioactive elements by massive stars. At present, there is no satisfactory model accounting for the presence of ^{26}Al in our Solar System. It might result from an improbable sequence of events, in which case the Solar System would be special in having hosted ^{26}Al while it formed. In such a case, our Solar System might be unlike others in having evolved (differentiated) parent bodies. Given that life, as we know it, is intimately linked to the geological history of our planet, it means that its development might result from a rare astrophysical event.

High-Temperature Processes in the Protoplanetary Disk

CAIs are very abundant in carbon-rich carbonaceous chondrites, while they are virtually absent from other chondrites. They are especially large and abundant in CV chondrites (► [Meteorite, Allende](#)). They therefore represent on the whole a tiny fraction of chondritic matter. Understanding

their formation is, however, important because they are the first solids to have formed in the protoplanetary disk. Their mineralogy is compatible with that of condensation from a gas of chondritic composition. Some of them show evidence of remelting and evaporation. It is widely believed that CAIs were formed close to the Sun (~ 0.1 AU), where temperatures in the disk were higher than 1600 K. They were subsequently transported to asteroidal distances, where chondrites formed, either by turbulent diffusion or via magneto-hydrodynamic winds rooted at the disk inner boundary.

Chondrules are far more abundant than CAIs. They make up to 80% of ordinary chondrites in volume. As ordinary chondrites represent more than 80% of the meteorites, chondrules were probably the most abundant solids in the disk. Some authors estimate that there might have been between 10^{24} and 10^{25} g of chondrules produced in the asteroid belt. Understanding how they were made from precursor solids and disk gas is therefore a key task of cosmochemistry.

It is widely believed that chondrules were heated up to ~ 2000 K on timescales of a few minutes and cooled relatively slowly (10–1000 K/h) compared to a cooling controlled by free radiation into space. Because of these short timescales, one speaks of flash heating. Most chondrules have been flash-heated several times, suggesting that a repetitive process was responsible for high-temperature processing. At present, the most popular mechanism for chondrules formation is the shockwave model, whereby a shockwave of speed ~ 10 km/s impacts dusty aggregates and heats them. The source of these shockwaves in the protoplanetary disk is not well identified. Gravitational instabilities, X-ray flares, and planetesimals supersonic motions have been proposed. All three models seem to face important difficulties.

Formation and Early Evolution of Telluric Planets

When the protoplanetary disk gas dissipated, we were left (in the inner Solar System) with a swarm of planetesimals and planetary embryos. It took

roughly 100 Ma to collect these bodies into the terrestrial planets we know, such as the Earth. Growth occurred through random encounters of embryos. Though many embryos contributing to a given planet came from its neighborhood (the feeding zone), a significant number of embryos came from more distant regions.

Though accretion was mostly constructive, some impacts were also partly destructive. It is widely believed that the Moon was made when a planetary embryo, roughly the size of Mars, hit the proto-Earth. The Moon was built from that embryo, sometimes called Theia, and the Earth's mantle. Thanks to the Hf-W isotopic system, it is possible to constrain that catastrophic event which gave birth to our satellite. Latest measurements suggest it occurred 62^{+90}_{-10} Ma after Solar System formation, taken as the CAI formation.

It is worth noting that dynamical studies demonstrated that the presence of the Moon stabilized the Earth's obliquity. Were the Moon absent, the Earth's obliquity would vary chaotically and Earth's climate would have been far less stable than it has been. This singular, hazardous, event might therefore have played an important role in the development of life as we know it.

While planets were forming, they developed a magma ocean and iron cores appeared. Measurements based on the Hf-W isotopic system demonstrated that the Martian core formation was completed 10 Ma after the start of the Solar System. At present there is no undisputed estimate for the age of the Earth's core.

The origin of the terrestrial atmosphere is an unsolved problem. It is a combination of delivery of volatile compounds from extraterrestrial matter and of a primordial, solar-type atmosphere trapped in the Earth's mantle and subsequently degassed. The excess of ^{129}Xe (daughter isotope of ^{129}I) in the Earth's mantle compared to the Earth's atmosphere indicates that the degassing occurred early, possibly during the first 150 Ma.

The origin of terrestrial oceans has long been debated. Because they have a hydrogen isotopic composition different from that of Earth water, long-period comets such as comet Halley probably did not contribute significantly to the water

budget. Jupiter-family comets and dark, water-rich asteroids are the best candidates. Their D/H ratio – measured in carbonaceous chondrites – is compatible with that of the terrestrial oceans. These celestial bodies might also have delivered organic matter which might have provided precursors to life chemistry. The timing of Earth's water delivery relative to the formation of the Moon is debated, though it seems pretty secure to state that water was delivered during the first 150 Ma.

At that point, all bodies were formed, and the architecture of the Solar System was only to be significantly changed once, during the Late Heavy Bombardment (LHB) 3.8 Ga ago. At that epoch, after 0.8 Ga of slow migration, the giant planets Jupiter and Saturn crossed a resonance and destabilized a disk of planetesimals, which were sent to the inner Solar System. Many of the large craters seen today on the Moon date from that time. It is actually thanks to the return of the Moon rocks and their detailed study that the LHB was identified. If there was any life present on Earth at that time, it may have been severely affected. Some other authors proposed that these impacts could have, on the other hand, stimulated life.

Future Directions

It is a challenging task to foresee the development of a scientific discipline whose future depends on the advancement of techniques, on the emergence of individuals, and on the general policy adopted by a few prosperous countries which might not remain so indefinitely. Some progress will be made on the – already populous – data collection front. That should serve to solve pending key questions such as the homogeneity of short-lived radionuclides or the locus and timing of organosynthesis. Instrumental developments should also help to revisit dogma that is rarely disputed, such as the flash-heating model of chondrule formation for which evidence is thin.

Laboratory experiments trying to reproduce key processes of the early Solar System should

also be developed. Condensation and evaporation experiments will illuminate the complex relationships between gas and solids within the protoplanetary disk and establish chemical as well as isotopic modifications induced by these fundamental processes.

An almost virgin direction of research is the study of the mechanical property of meteorites. Very little is known, for example, on their tensile strength which is key to our understanding of planetary accretion and evolution. Such measurements are desperately needed in the light of several space missions.

It is striking that, while a great deal is made of deuterium (^2H) and ^{15}N excesses in organic matter, the processes that gave rise to them are still debated. Developments on the modeling front are highly needed.

Cosmochemistry will certainly benefit from increased interaction with astrophysics. Observations of star-forming regions can be seen as a proxy of the environment of our Solar System formation. Thanks to space telescopes, such as *Herschel*, or ground-based interferometers, such as [ALMA](#), our understanding of accretion disks will be bettered, enabling us to “see” closer to the central star, in regions where precursors of planets similar to the Earth might form. Theoretical astrophysics should be a daily companion of cosmochemists, and one could dream of a world in which most, if not all, data collected are interpreted within a theoretical framework.

One exigency could represent a horizon for cosmochemistry: that of holding things together. Too many disparate interpretations coexist without being really coherent one with the other. Though some patches of the jigsaw puzzle have been thoroughly assembled and though the global vision is probably correct, many of the data collected find no explanation within our current knowledge. In that respect, astrophysics will, as always, teach us humility. Though there is no reason for our Solar System to be special, there are many possible outcomes of star and planetary formation. Ours is one among billions in the Galaxy.

Cosmogony

Daniel Rouan
LESIA, Observatoire Paris-Site de Meudon,
Meudon, France

Definition

A cosmogony is any theory about the origin of the universe and/or the objects it contains. Most cultures developed their own cosmogony. In astronomy, the term usually refers to theories of formation of the solar system.

Definition

Cosmogony is a theory about the origin and development of the cosmos or universe. The word comes from the Greek κοσμογονία (from κόσμος “cosmos,” “the world”) and the root of γί(γ)νομαι/γέγονα (“to be born, come about”). It is different from cosmology, which is the study of the universe structure as a whole. Cosmos is not only a word for matter but for order, for process.

History

There are two types of Greek cosmogonies. One, mythical, is very similar to the Mesopotamian myths, based on a divine couple who give birth to all beings. The second, introduced by the Greek philosophical tradition, is the first intellectual approach based on evidence, reason, and debate.

But the earliest speculations were still consistent with the mythical world structure.

Overview

First Mythical Cosmogonies

Hesiod's *Theogony* (Θεογονία), written in the sixth century BC, is the first Greek mythical cosmogony: it is a large-scale synthesis of Greek traditions concerning the gods. In the language of the Archaic period (eighth to sixth century BC), *arche* (ἀρχή) designates the source, origin, or root of things that exist. If a thing is to be well established or founded, its *arche* or static point must be secure, and the most secure foundations are those provided by the gods: the indestructible, immutable, and eternal ordering of things. The initial state of the universe or the origin (*arche*) is Chaos (χάος): a gaping and indefinite void considered as a divine primordial condition from which everything else appeared. Hesiod gives no idea about what preceded the appearance of Chaos.

Chaos was the first of the primordial deities, followed by Gaia (Mother Earth), Tartaros (the underworld), the later-born Erebus (the darkness between the earth and underworld), and Nyx (Night). Eros is sexual desire – the urge to reproduce, not the emotion of love, as is the common misconception. Erebus and Nyx reproduced to make Aether (the outer atmosphere where the gods breathed) and Hemera (Day).

Gaia was the Protogenos (primeval divinity) of earth, one of the primal elements who first emerged at the dawn of creation, along with air, sea, and sky. She was the great mother of all palpable beings: the heavenly gods were descended from her union with Ouranos (the Sky), the sea gods from her union with Pontos (the Sea), the Gigantes from her mating with Tartaros (the hell pit), and mortal creatures were sprung or born from her earthly flesh. With a cosmic order under the presence of Zeus, cosmogony is complete.

But we also know the existence of variant cosmogonies. In Homer's *Iliad* (XIV, 210–246)

and later authors, Hera qualifies Oceanus and Tethys as the “father and mother of gods,” the primordial couple. This can establish an allusion to a different cosmogony where primordial chaos is watery.

The Orphism (known by orphic fragments, Greek hymns C3rd–C2nd BC), the religious trend which took place away from the traditional practices of the cult, developed several cosmogonies. It is placed at the origin of the universe the Night or the Time, which engenders a world egg, primordial mixture of elements, which gives birth to Gaia, Chaos, and Phanes, the primeval god of procreation, the driving force behind reproduction in the early cosmos. Phanes was the first king of the universe, who passed the royal scepter on to his daughter Nyx (Night), who in turn handed it down to her son Ouranos (Heaven). From him, it was first seized by Khronos (Time) and then by Zeus, the ultimate ruler of the cosmos. Phanes also incorporated the aspects of other primordial beings described by various ancient writers, including Thesis, Phusis, Ophion, Khronos, and Ananke. All these gods are concepts rather than real characters.

Representations of Mother Earth and Phanes

In Greek cosmology, Earth was conceived as a flat disk encircled by the river Okeanos and topped above by the solid dome of heaven and below by the great pit of Tartaros. She herself supported the sea and mountains upon her breast.

Mother Earth's personification of the soil-ground whose products support human existence, a cosmogonical symbol of the material aspect of the universe, was depicted as a buxom, matronly woman, half risen from the earth in Greek vase painting and Roman mosaics (see ► [“Cosmogony: Rome”](#)). She was portrayed as inseparable from her native element.

Phanes was portrayed as a beautiful, golden-winged hermaphroditic deity wrapped in a serpent's coils. The poets describe him as an incorporeal being invisible even through the eyes of the gods. His name means “bring to light” or “make appear” from the Greek verbs, *phanaō* and *phainō*.

Birth of Philosophical Cosmology

There were many pre-philosophical cosmogonies among the ancient Greeks, but the pre-Socratics and the Atomists differed fundamentally from all of them by seeking the origin of the world on a rational basis rather than by appealing to a supernatural force.

Their understanding of the world applies the idea of order and harmony of a cosmos in all the elements that have to obey physical and mathematical laws. The Greek science tries to report most rationally the possibility of appearances observed in the sky, by elaborating explanatory models which allow to foresee the return.

All of the pre-Socratics, only known by fragments, held that the cosmos has a beginning. *Arche* is basic stuff of the universe, the element and the first principle of existing things. This is considered as a permanent substance or nature (*physis*), either one or more which is conserved in the generation of the rest of it. From this, all things first come to be and into this they are resolved in a final state. This source of entity is always preserved (Aristotle, *Metaph.A*, 983, b6ff).

For Thales of Miletus (c. 624–547 BC), the *arche* is water. His theory was supported by the observation of moisture throughout the world and coincided with his theory that the earth floated on water. His ideas were influenced by the Near-Eastern mythological cosmogony and probably by the Homeric statement that the surrounding Oceanus (ocean) is the source of all springs and rivers.

Anaximander of Miletus (610–545 BC) believed the beginning or ultimate reality is eternal and infinite, or boundless (*apeiron*), subject to neither old age nor decay, which perpetually yields fresh materials from which everything we can perceive is derived.

Apeiron generated the opposites, hot-cold, wet-dry, etc., which acted on the creation of the world. Everything is generated from *apeiron* and then it is destroyed there according to necessity. It acts as the substratum supporting opposites, such as hot and cold and wet and dry, and directs the

movement of things, by which there grew up all of the hosts of shapes and differences which are found in the world. Out of the vague and limitless body, there sprang a central mass – this earth of ours – cylindrical in shape. A sphere of fire surrounded the air around the earth and had originally clung to it like the bark round a tree. When it broke, it created the sun, the moon, and the stars.

Anaximenes of Miletus (588–524 B.C.) posits air as the *arche* and ascribes to it divine attributes; he provides a theory of change and supported it with observation. Using two contrary processes of rarefaction and condensation (thinning or thickening), he explains how air is part of a series of changes. Thinned air becomes fire and when condensed becomes first wind, then cloud, water, earth, and stone in order.

For Heraclitus of Ephesus (540–480 BC), *arche* is fire. For Empedocles, it is composed of some combination of four elements: earth, water, fire, and air. He is claiming that the primary opposites, hot and cold and wet and dry, evolved from these principles and that the other parts of the cosmos evolved from these opposites. For the Atomists (Leucippus (fl. 430 BC) and Democritus (460–370 BC), the universe contains an infinite number of such indestructible beings, “atoms”; space (as void) is not continuous, since where atoms are, void is not.

The generation of the gods is described by Plato (427–346 BC); but the origin of the cosmos is philosophically explained by him, in the same work, as the result of the planned actions of a constructor or demiurge. He conceived the earth as a sphere at the center of the world. Aristotle taught that matter had natural motions depending on its composition. The questions about the earth were summarized by Aristotle (*On the Heaven* 1956, II 293a) with the question of the place of the earth in the universe, of its shape, and of its size.

Cosmogony: Mesopotamia

Gregory Chambon

Faculty of Arts and Humanities, Ecole des Hautes Etudes en Sciences Sociales, Paris, France

Definition

Cosmogony is a narration about the origin and development of the cosmos or universe. It is different from cosmology, which is the study of the structure of the universe as a whole.

History

In Mesopotamia, the interest was more about the origins and functions of gods than about the origins of universe and life.

“Water” was the prime element in all the traditions of Mesopotamia (Sumerians, Akkadians,

Hittites, Assyrians, etc.), and the roles of Tigris and Euphrates were particularly central in mythological texts.

Overview

In Mesopotamia, it seems at first glance that a much greater interest was taken in the origins and functions of the gods than in the processes whereby the universe originated. The Mesopotamian myths and rituals do not actually deal with *how* and *why* the world was formed but rather *how* and *why* gods created specific things like human beings and living nature. In order to approach this ancient thought concerning the origin of the cosmos, we have first to understand the different cosmogonic associations between a deity and prime elements of the universe. These associations may vary by regions and traditions over a period of more than 2500 years of Mesopotamian history, within different cultures (Sumerians, Akkadians, Hittites, Assyrians, etc.).

One of the main prime elements in these traditions is “water.” The terms used in mythological text are often Sea and River, which refer directly to the geographical description of Mesopotamia with the main rivers, Euphrates and Tigris, and the Arabic and Mediterranean seas. The Babylonian creation epic *Enuma Elish*, so-called from the first two words of the poem “When on High” and probably composed in the early part of the second millennium BC, describes how, during the very first separation of order out of watery chaos, the primeval parents of the gods, Apsû (sweet waters underground) and Tiâmat (the sea), mingle their waters together and create the second generation in the theogony. This second generation kills Apsû, who planned to destroy his descendants, and asks Marduk, god of Babylon, for help and sent him against Tiâmat. Armed with his winds and storms, he slices Tiâmat’s body in half, forming Heaven with the upper part and Earth with the lower. Her members were used to supply its physical features: the Tigris and Euphrates flow from her two eyes, the bases of the Mountains

were formed from her breasts, and her tail becomes the Milky Way. The remainder of the story in the creation epic deals with Marduk's organization of the cosmos with the offices that he assigns to the other gods and his creation of man. The contrast between the old chaos and the present order of the cosmos is underlined by the difference of "dynamic" by the gods: the second generation of the theogony is considered as a generation of dynamic and moving gods, whereas the chaos creatures Apsû and Tiāmat stand for inertia and rest.

Others poems and epics show that Mesopotamian tradition considered the physical universes as a superimposition of levels. Above an underworld at the bottom, Apsû could be found as the dead body of the chaos monster of that name and ruled by Ea, the god of wisdom, crafts, and creation. The second level consisted of the Earth, where men were living and which was controlled by Enlil, the god of breath and wind. The stars moved in an orbit above space, separating the lower parts from their upper counterparts. Two heavens were situated at the top of these levels: the upper one was ruled by An, god of Heaven.

Definition

Cosmogony is a theory about the origin and development of the cosmos or universe. It is different from cosmology, which is the study of the structure of universe as a whole.

History

Roman cosmogony is founded on those of earlier classic age. The Romans took over Greek myths and philosophic science (see Cosmogony: Greece) but added nothing to Greek cosmogony. The Hellenistic view was relatively unchallenged until the time of Nicolaus Copernicus (1473–1543) and Galileo Galilei (1564–1642).

Overview

Roman cosmogony is depicted by Ovid (43 BC–AD 17) in the *Metamorphoses* 1.1. He described Chaos as “a rude and undeveloped mass, that nothing made except a ponderous weight; and all discordant elements confused, were there congested in a shapeless heap” (see Cosmogony: Greece). Like ancient Greeks, Romans begin the genesis of gods and nature with a feminine entity, Gaia, which appears after Chaos and before Eros. Chaos contains primitive elements (earth, water, air, and fire). Gaia is a natural element which produces and supports the world. In Ovid, an unknown god organizes all these elements, and

Cosmogony: Rome, Fig. 1 Roman mosaic from a Roman villa in Sentinum (now known as Sassoferrato, in Marche, Italy), (ca. 200–250 A.D., Glyptotek Munich, Inv. W504). The Mother Earth goddess, Tellus, is sitting with four children, who represent the four seasons. Aion, the god of eternity, is standing inside a celestial sphere decorated with zodiac signs, in between a green tree and a bare tree (summer and winter)

living beings occupy ether and stars (gods), air (birds), water (fishes), and earth (animals and men).

In the first century AD, Roman people pictured the Mother Earth, supreme goddess of the earth (Roman counterpart of Gaia) (Terra Mater/Tellus), as a sweet mother: her role is reduced to the dream giving and to the feeding of plants and children. *Tellus* thus refers to the guardian deity of Earth and by extension, the globe itself. The attributes of Tellus were the cornucopia or bunches of flowers or fruit. She was typically depicted reclining. In mosaic art, Gaia appears as a full-figured, reclining woman, often clothed in green, and sometimes accompanied by grain spirits – the Karpoi (e.g., in Antakya Museum, inv. 847, the fourth century) (Fig. 1).

Cosmology · Americas

Definition

Indigenous American cosmologies are archaic, integrated worldviews conceived by the ancient and protohistoric peoples of the Americas prior to substantive contact with European peoples in the sixteenth century. The cosmos in these worldviews usually comprises several layered and axially organized realms. Rooted in observation and interaction with nature, these cosmologies portray the primary components of the environment, including the sky, the ground, the subterranean realm, the waters, atmospheric processes, plants, animals, and more, as an integrated system energized and managed by the power of spirits and gods. The structure and order attributed to the cosmos underpins a system of thought that

orders the social structure, political mechanisms, the economy, and religious expressions of the community.

Overview

There is no room in the indigenous cosmologies of the Americas for the plurality of worlds and extraterrestrial life. These traditional cosmologies are delineated in mythic narrative that does not engage physical law, the geography of outer space, and modern astronomical knowledge.

The most fundamental character of these traditional cosmologies is the same throughout the Americas and, in fact, beyond. Although the exact architecture may differ from culture to culture, and even within a culture over time and distance, each of these conceptual structures acknowledges three primary realms – the surface of the earth, the upper world of the sky, and the lower zone of the underworld (Fig. 1).

Rooted in an animist sensibility, the indigenous Americans north of Mexico, in Mesoamerica, and throughout South America understood the world to be fortified with power controlled by spirits that attend singular places as well as defined territories and natural environments. In this traditional cosmovision, celestial objects are not places but animate beings, and often personified powers – spirits and gods – require attention and warrant caution.

Some of the indigenous peoples of the Americas linked the creation and the peopling of the world to “sky people” and celestial gods, while others did not. Celestial divinities in the Americas are neither a necessary nor sufficient condition for the creation of life in these mythic tales.

In detail, the ancient perspective on the sky was modulated by many factors, including geographic latitude, climate, subsistence pattern, social complexity, and historic circumstance. The sky was not extraterrestrial real estate but rather an essential domain of a bounded and finite cosmos centered on the world inhabited by people, animals, and plants. Through celestial events, the sky helped disclose nature’s cyclical patterns, define

Cosmology: Native American, Fig. 1 The sky, the ground, and the underworld are fundamental elements of traditional cosmologies worldwide. The drawing on this Siberian shaman’s drum depicts the structure of the cosmos in Siberian belief. The sky is the realm above the horizontal line, and it is populated with rayed celestial objects and a circle that represents the “hole” in the sky, the north celestial pole, which is at the summit of the vertical axis that extends down to the terrestrial world, inhabited by animals, plants, and a drum-carrying shaman, and terminates at the bottom in an aperture to the underworld (Griffith Observatory illustration)

the frame of the cosmos, sustain the social fabric, and put a lid on personal experience of the universe. It helped demonstrate the connection between the cosmic and the divine. It integrated society and individual destiny. It revealed the world’s center and edge.

Lifestyles and topography prompt anthropologists to divide indigenous North America north of Mexico into 11 cultural regions: Arctic, Subarctic, Northwest Coast, California, Southwest, Plateau, Plains, Southeast, and Northeast. Each of these, in turn, is subdivided into tribal territories. Great differences in ways of life are evident among all

of these Indian peoples, but they share the fundamental concept of a more or less flat earth – often imagined to be a disk – sandwiched between the subterranean world and the sky. It is a static cosmos that changes cyclically but remains fundamentally the same, although sometimes long-term cataclysmic transformations are projected onto the mythic past and anticipated in visions of the future.

In the Arctic, the Inuit saw the world operating according to the principles of a traditional cosmos. They recognized multiple layers in the sky – as many as five. Each is a tenanted realm that superficially resembles the earth, and each has another sky above it. Some Inuit say the stars are actually holes in the canopy. Light from the higher realm pours through the celestial colander. Shamans who visit those supernal precincts pass through the holes, especially the aperture closest to the pole of the sky, and gain access to the spirits of the next heaven. Alternatively, other Inuit believe the stars are people and creatures luminously transformed. Personifying the sun and the moon as sister and brother, the Inuit regard them as glowing disks who circle through the upper sky (Fig. 2).

The Seneca, an Iroquoian people in Western New York, attribute the world's creation to a woman in the sky world. This Northeast tribe identifies her as the wife of the Great Chief of the Sky. Angered by the accidental uprooting of the sky world's Tree of Life, the Great Chief pushed his young spouse through the hole left in the sky by the tree's removal. The tree was the source of everything that grows, and as the woman slipped over the edge, she grabbed a fistful of seeds and then fell toward the primordial waters below. She was caught in midair, however, by ducks that had been swimming on the face of the deep, and they set her down upon the back of a vast turtle that emerged from below. A muskrat dredged mud from the bottom, covered the turtle's shell with it, and created an island, which was seeded by the fallen woman and transformed into the world we know (Fig. 3).

The Wyandot, or Huron, also spoke an Iroquoian language and resided in the Great Lakes area. According to Wyandot myth, the

Cosmology: Native American, Fig. 2 Multiple levels of the Inuit cosmos are references in this moon face mask from Alaska. The ring around the face symbolizes one of those realms, and the feathers stand for stars. The four holes are passages through which animal spirits descend to earth from the sky. (Photograph E.C. Krupp, University of Pennsylvania Museum of Archeology and Anthropology)

world was originally almost nothing but water, and the Wyandot lived in the sky. There were no sun, moon, or stars, and the cosmos was lighted instead by a tree near the lodge of the Sky Chief. In a narrative that parallels and amplifies Seneca myth, an ordered cosmos is eventually constructed, and it is driven by complementary oppositions: light and dark and summer and winter. It has a sky world with two levels, a solid earth, a subterranean land for the dead, deified forces of nature, and personified celestial objects.

In the Pacific Northwest, the Kwakiutl of British Columbia constructed their cosmos with the usual three levels. The sun, the dawn, the thunderbirds, and other celestial beings resided above the clouds in an axial universe that skewered the three layers on a copper pole that supports each one in place.

On the Great Plains, the Sioux imagined a layered universe with four levels above the ground and four below.

The Woman who fell down from Heaven

Cosmology: Native American, Fig. 3 In Iroquoian myth, the tale of the woman who fell from the sky accounts for the Creation of the world below. The Wyandot (Huron) version of the story is illustrated by William Wallace Clark in *Indian Myths*, published in 1928. The woman is suspended here between the sky and the lower waters, over which the thunder god is rolling and throwing lightning, and land has begun to form (Collection E.C. Krupp)

The Creek Indians, a Southeast tribe originally settled in Georgia and Alabama, judged the world to be flat and square. The sky was roofed with a solid vault, and the celestial domain belonged to meteors, the Milky Way, the moon, and the sun. The god of the sky and some of the spirits of the dead lived on the dome. An underworld, or perhaps a series of them, lay beneath the earth.

According to María Solares, an Ineseño Chumash, who lived in southern California until her death in 1922, “There is this world in which we live, but there is also one above us and one below us.” Two giant snakes support the flat earth in the underworld, and when they move, they cause earthquakes. The Sky People include Sun, Morning Star, Sky Coyote, Evening Star, and Moon, and they live in houses in the upper

Cosmology: Native American, Fig. 4 The Chumash of southern California imagined the earth as island surrounded by oceanic waters. Celestial objects, including the Sun, the Moon, the Morning Star, and the North Star, reside in the upper world. Two great snakes support the underground world below the earth (Collection E.C. Krupp)

world. All of the worlds of the universe are flat and circular, with one positioned directly above another. Sun is an old man who daily carries a torch across the sky. Moon is a woman and the independent scorekeeper of the annual gambling game that determines what our world can expect from the Sky People each year (Fig. 4).

In Mesoamerica, cosmological traditions of the Aztecs, the Maya, and others survived the Spanish Conquest and confirmed the prevailing notion of a multilevel, axial stack of worlds with the inhabited earth in the middle of the universe with one foot at the bottom of the heavens and the other at the top of the underworlds. The earth, in this scheme, is the upper surface of a solid disk ringed by waters that pool outward as far as the horizon, where they blend with the sky. The Aztecs divided the disk into quarters, each of which was associated with a cardinal direction – north, south, east, and west.

The *Codex Vaticanus A*, a post-Conquest illustrated manuscript from sixteenth-century central Mexico, depicts the Aztecs’ layered universe. There are 13 “heavens” and 9 underworlds, and the earth is counted as both. The second layer of the sky is the Paradise of the Rain God and the track through which the moon moves. The stars and Milky Way are in the third level, and the sun travels through the heaven above that. The next

Cosmology: Native American, Fig. 5

The layered cosmos of ancient Aztecs of central Mexico is a skyscraper with 13 upper stories that share the floor at ground level with the nine basements. The levels of this universe are identified and illustrated in *Codex Vaticanus A*, or *Codex Rios*, a sixteenth-century manuscript written in Italian and thought to be a copy of a lost indigenous original. The treatise deals with Aztec religion, history, customs, and calendar (Illustration Griffith Observatory, Joseph Bieniasz, after *Codex Vaticanus A*)

floor accommodates the salt-fertility goddess and probably Venus, and the story over that is dedicated to the fire drill constellation (Orion's belt and sword) and comets. Beyond Orion are the Black Heaven of winds (#7), the Blue Heaven of dust (#8), the Place of Thunder (#9), the White

God Place (#10), the Yellow God Place (#11), the Red God Place (#12), and the Place of Duality (#13), where the remote divine couple who parents gods and people presides.

The second underworld layer of the stratified Aztec cosmos, just beneath the earth disk, is the

Cosmology: Native American, Fig. 6 The Maya and other peoples of Mesoamerica incorporated a solar metaphor into the architecture of their traditional universe and likened the levels of the sky and the underworld to the sun's daytime ascent and descent and to an imagined

descent into and emergence from the underworld at night. Late indigenous sources assign 13 steps to the day and 9 steps to the night. The concept parallels the layered architecture of the pyramids built in ceremonial centers (Illustration Griffith Observatory)

Water Passage, and the Place Where Hills Clash Together (#3) is below that. In descending order, the rest of the underworlds include Obsidian Knife Hill (#4), Place of the Obsidian-Bladed Wind (#5), Where Banners Are Flourished (#6), Where Someone Is Shot with Arrows (#7), Where Someone's Heart Is Eaten (#8), and the Place of the Dead Where the Streets Are on the Left (#9). All of the underworlds are dangerous, and most involve sacrifice or death (Fig. 5).

No comprehensive, detailed, and explicit accounts of traditional central Mexican cosmology exist, and other fragmentary sources suggest at least one other, and likely older, version of the layered universe was embraced. More like a multileveled pyramid, this alternate universe

ascended in nine platforms that were associated with the daily ascent of the sun. An inverted, nine-level pyramid extended in the opposite direction, directly below the earth. In a similar way, it echoed the sun's nightly passage into and out of the underworld. The watery stream that encircles the earth disk and belts this pair of opposed pyramids around the middle was called "Nine Stream" in deference to the nine levels of day and the nine levels of night (Fig. 6).

The Castillo, or Temple of Kukulcán, the primary pyramid at Chichén Itzá, in northern Yucatán, is in Maya territory, but it belongs to the Post-Classic era, which was strongly modulated by central Mexican iconography and architectural conventions. Built in the eleventh century

Cosmology: Native American, Fig. 7 Mesoamerican pyramids appear to miniaturize the cosmos through symbolic architecture. Some Maya are believed to have assigned nine levels to heaven and nine levels to the underworld. The nine levels of the Castillo, or Pyramid of Kukulcán, of Post-Classic Chichén Itza, in northern Yucatan, transform the design of the site's primary

ceremonial building into the structure of the cosmos. The display of luminous triangles on the balustrade of the north stairway also mimics the diamondback appearance of the Feathered Serpent, Kukulcán, close to sunset at the equinoxes, after the sun has ascended from the eastern horizon and as it approaches the western horizon. (Photograph E.C. Krupp, 20 March 1982)

Cosmology: Native American, Fig. 8 The Kogi assign four levels to the upper or “day” world that is affiliated with the sun and four levels to the subterranean “night” world. Our world is in the middle of this spindle of worlds (Illustration Griffith Observatory, after Gerardo Reichel-Dolmatoff)

A.D., it is a stack of nine levels of symbolic monumental architecture that miniaturizes the Maya cosmos and puts the sun’s daily endeavor on public display in a ritual environment (Fig. 7).

Elsewhere in southern Mexico and western Central America, some Maya peoples also portrayed the universe as a kind of stepped pyramid, and different communities adopted differing tallies of the layers. The heavens vary from 3 to 15. The Lacandón, in Chiapas, appear to have inherited some of the archaic traditions of the southern Maya, and they picture a seven-tier cosmos with five heavens, the earth, and one underworld, all piled up like a stack of floating plates. The upper heavens are negotiated by the sun, moon, and stars.

The indigenous cultures of South America, like those of North America and Mesoamerica, are numerous and disparate, but just a sample of traditional South American cosmologies demonstrates they conform to the basic principles of indigenous cosmologies elsewhere in the Americas and, for that matter, in most of the rest of the world. The Kogi, in northern Colombia’s

mountains, see the cosmos as a spindle and relate the sky's motions to weaving. There are nine levels in this axial, layered universe: four heavens, the flat central disk of the earth, and four underworlds (Fig. 8).

The Inca, who established an empire centered in Andean Peru, are the best known pre-Columbian people of South America. They and their current Quechua descendants divide the cosmos into the earth, a subterranean world beneath the earth, and a celestial realm above it. Today's Quechua in Andean farming villages say the sun moves through the world below at night and the waters of the Milky Way circulate between the sky and the cosmic ocean that surrounds the world and flows beneath it.

Key Research Findings

While “extraterrestrial” realms are fundamental components of the indigenous cosmologies in the Americas and the rest of the world, these places are not other worlds where conditions on earth are imagined to be duplicated in a way that would sustain biological life. They are instead transcendent territories that are traveled by gods, ruled by spirits, visited by shamans, and occupied by the dead, and the celestial lights modern astronomy identifies as physical components of the solar system are powerful gods who make the world the way it is.

COSPAR

Catharine A. Conley
NASA Headquarters, Washington, DC, USA

Definition

After the USSR launched its first Earth satellite in 1957 and thereby opened the space age, the International Council of Scientific Unions (ICSU), now the International Council for Science, established its Committee on Space Research (COSPAR) during an international meeting in London in 1958.

COSPAR's objectives are to promote on an international-level scientific research in space, with emphasis on the exchange of results, information, and opinions, and to provide a forum open to all scientists. These objectives are achieved through the organization of Scientific Assemblies, publications, and other means. COSPAR's first Space Science Symposium was organized in Nice in January 1960. Now general assemblies are organized every other year.

In its first years of existence, COSPAR played an important role as an open bridge between East and West for cooperation in space. When this role became less prominent with the decline in rivalry between the two blocs, COSPAR, as an interdisciplinary scientific organization, focused its objectives on the progress of all kinds of research carried out with the use of space means (including balloons).

These activities are divided in “commissions,” and inside the commission F is dedicated to life sciences and subcommission F3 is devoted to astrobiology.

COSPAR has also concerned itself with questions of biological contamination and spaceflight while exploring the solar system. This proceeds from Article IX of the Treaty on Principles Governing the Activities of States in the Exploration and Use of Outer Space, Including the Moon and Other Celestial Bodies (also known as the UN Space Treaty of 1967). COSPAR, based on the work of a dedicated planetary protection panel, proposes and maintains a planetary protection policy for the reference of spacefaring nations.

[European Cooperation in Science and Technology](#)

Definition

COST is a program of the European Union (EU) designed to support transnational cooperation

in science and technology. It was established in 1971 to foster scientific excellence and increase the mobility of researchers across Europe. COST features three main elements: geographical spread, involving member states that are currently less research-intensive; involving early career investigators; and promoting gender balance. To reach its goals, COST funds COST Actions, which seek to allow European researchers to network and develop ideas in any field of science and technology.

History

In 2013, the COST Action “Life Origins” was approved for the period 2014–2018, with the objective of addressing fundamental questions about the origin, evolution, and distribution of life in the Universe.

of Technology, Atlanta, GA, USA

Definition

Covalent bonds are molecular bonds formed via the sharing of electrons, according to Lewis rules,

to form closed electron shells of two, four, or six electrons (for single, double, or triple bonds, respectively). They are differentiated from ionic and ► [weak bonds](#) by the amount of energy required to break them, typically on the order of 150–1000 kJ/mole ($\sim 1.5\text{--}10$ eV/mole), depending on the species. Covalent bonds tend to form between atoms of similar electronegativity. Covalent bonds formed between atoms of dissimilar electronegativity (i.e., C–Cl) will be polar, with a greater amount of the electron density centered around the more electronegative nucleus.

Crater Lakes (Mars)

Alessandro Airo

Institut für Geologische Wissenschaften Tektonik und Sedimentäre Geologie, Berlin, Germany

Definition

It is widely accepted that liquid water was present on the surface of ► [Mars](#) during its early history. Consequently, this surface water must have migrated downhill, accumulating in topographic depressions. Besides the ocean-size northern lowlands, the most prominent basins on Mars are the numerous impact craters. There is much evidence for prolonged water ponding within individual or interconnected impact craters, such as (1) channels leading into the craters and having deposited delta

fans, (2) the presence of paleoshorelines along the crater walls, or (3) the occurrence of horizontally layered deposits composed of phyllosilicates or sulfates interpreted to represent lacustrine sediments and evaporites (e.g., Michalski et al. 2013; Pondrelli et al. 2005).

Although there are no substantial amounts of liquid water on Mars' surface today, a sufficiently large impact into ground-ice baring terrain could potentially create a transitional crater lake. Impact-induced ground-ice melting is supported by the presence of fluidized ejecta around rampart craters, which are thought to require liquid water for their formation (Mouginis-Mark and Boyce 2012). Under current Mars conditions, a lake would quickly freeze at the surface, but modeling studies predict that such an ice layer would protect the underlying water from rapid evaporation and therefore preserve the lake for up to a few hundreds of thousands of years (McKay and Davis 1991). Furthermore, it can be assumed that the impact-related heating of the crater floor would delay the freezing of the entire lake water and potentially drive long-term hydrothermal circulation.

Asteroid · Collision · Comet · Impact · Micrometeorite · Surface

Definition

An impact crater is a mostly circular or elliptical elongate depression, generally with a raised rim, which is created by the impact of a minor body on the solid surface of a ► [planet](#) or satellite. Impact craters range in size from microcraters seen only microscopically on surfaces of ► [rock](#) samples (e.g., rocks from the lunar surface) to large craters and ► [impact basins](#) several hundreds or thousands of kilometers across. Impacts into the atmospheres of the large gaseous planets in the outer ► [Solar System](#) can produce transitory circular or semicircular features resembling craters, as has been observed on ► [Jupiter](#) after the impact of ► [Comet Shoemaker/Levy-9](#).

Overview

Impact craters on solid surfaces of planets and satellites are created by hypervelocity collisions with smaller bodies. These bodies, termed *impactors* or *projectiles*, range in size from ► [micrometeorites](#) to large bolides up to tens or hundreds of kilometers in diameter, which form impact basins several hundreds or thousands of kilometers across (Pike 1980; Melosh 1989). Candidate impactors are (1) ► [asteroids](#) from the main belt (MBA) or from other asteroid families, for example, Near-Earth asteroids (NEA) (Neukum et al. 2001; Strom et al. 2005; Bottke et al. 2012), (2) ► [comets](#) including ► [ecliptic](#) or short-period comets (EC, orbital period <200 years) derived from the ► [Kuiper belt](#) and

nearly isotropic or long-period comets (NIC, orbital period >200 years) from the ► [Oort cloud](#) (Zahnle et al. 2003), (3) bodies or debris in planetocentric orbits (Neukum 1985; Chapman and McKinnon 1986), and (4) remnants of planetary accretion (planetesimals) (Wetherill 1975).

The number or frequency of craters on a surface per unit area records its age: the higher the crater frequency, the older the age of the surface due to the longer exposure time to the incoming impactor flux. This relationship can be used as an important tool in planetary chronology.

Morphology and sizes of impact craters reflect impact conditions, projectile properties, target properties, and changes of target properties with time (Schenk et al. 2004). The smallest craters identified in camera images are simple craters, characterized by a bowl-shaped, parabolic crater morphology (e.g., Melosh 1989). With increasing diameter, crater forms become more complex. The simple-to-complex transition diameter approximately scales with the inverse of the gravity acceleration, except for icy surfaces as on ► [Mars](#) (ice in the regolith) and the icy satellites in the Outer Solar System (Chapman and McKinnon 1986; Melosh 1989; Schenk et al. 2004). Features observed in complex craters include (Pike 1980; Chapman and McKinnon 1986; Melosh 1989; Schenk et al. 2004) (a) flat crater floors, (b) terraces at crater wall interiors, (c) central peaks, or (d) peak rings. On icy satellites, complex crater forms include (e) central pits (also observed on Mars [e.g., Barlow 2009]), (f) central domes, or (g) bright, almost flat circular areas termed *palimpsests* (Faculae) devoid of prominent topographic features such as crater rims.

The largest impact structures are ► [impact basins](#), which exhibit two or even more rings (ridges or graben) and are termed multi-ring basins (e.g., Spudis 1993).

Craton

Nicholas Arndt

Emeritus Professor, ISTerre, University Grenoble Alpes, Grenoble, France

Definition

A craton (from the Greek *kratos* – force) is an old, thick, cool, and rigid part of the continental lithosphere. Its crustal part is typically composed of granitoids, and high-grade, strongly deformed, metamorphic rocks and less metamorphosed meta-volcanic and metasedimentary rocks (greenstone belts). The crustal section of a craton is thicker than that of normal continental crust (which is ~30–40 km) and is underlain by a thick (up to several hundred km) root of low-density, depleted lithospheric mantle. Cratons formed through orogenies (mountain-building processes) and accretion of crustal fragments during the Archean eon when mantle and crustal temperatures were higher than those of today. When covered by younger sedimentary basins, they are referred to as platforms. Examples of well-known Archean cratons are the Slave Craton of Northwest Canada, the Pilbara Craton of Northwest Australia, and the Kaapvaal Craton of Southern Africa.

Crenarchaeota

Ricardo Amils
Departamento de Biología Molecular,
Universidad Autónoma de Madrid, Madrid,
Spain

Definition

Crenarchaeota is one of the first phyla described for ► [Archaea](#). Crenarchaeota comprises both hyperthermophilic and cold-dwelling prokaryotes. The hyperthermophilic species of Crenarchaeota tend to cluster closely together and occupy short branches on the 16S rRNA gene phylogenetic tree. These organisms are considered good models for early Archaea. Phylogenetically, these are a more rapidly evolving species. Most hyperthermophilic Crenarchaeota have been isolated from geothermal heated soils, waters containing elemental sulfur and sulfides, or hydrothermal vents. Among the hyperthermophilic Crenarchaeota, we can find members of the Sulfolobales, Thermoproteales, and Desulfurococcales orders. One species of *Sulfolobus*, *S. acidocaldarius*, was the first hyperthermophilic Archaea discovered. It was isolated by Thomas Brock and colleagues in Yellowstone National Park, USA, in 1970. Special mention should be given to *Pyrodictum fumarii*, which can grow at 113 °C.

CRISPR

Lluís Montoliu
National Centre for Biotechnology (CNB-CSIC),
Madrid, Spain

Keywords

Genome · Repeated DNA · Nuclease ·
Antiviral · Bacteriophage · Virus · RNA

Synonyms

[CRISPR/Cas](#); [CRISPR/Cas9](#)

Definition

CRISPR is an acronym standing for Clustered Regularly Interspaced Short Palindromic Repeats, and refers to a genomic pattern found in bacteria and archaea of adjacent unique and repetitive

alternating DNA fragments, constituting the genetic compound of an ancestral adaptive immune system used by prokaryotes to fight against bacteriophages and plasmids. A set of CRISPR-associated (Cas) proteins, most with nuclease-type activities, represent the effector compound of this system. Currently, there are at least two classes, six types and 33 subtypes of CRISPR-Cas systems. About half of the bacteria and more than 80% of archaea carry at least one CRISPR-Cas system.

History

The acronym CRISPR was invented by Francis J.M. Mojica, a microbiologist from the University of Alicante (Spain) and was first used in a scientific publication in 2002 by Ruud Jansen and collaborators in *Molecular Microbiology*. Mojica was also the first to foresee the function of these curious genomic arrangements in 2005. He realized that the unique DNA sequences in between repetitive fragments found in the CRISPR arrays were, actually, fragments of bacteriophage genomes. He also observed that bacteria and archaea carrying genomic pieces of some viruses were resistant to infection by the same viruses. These observations led him to propose that CRISPR arrays would be part of an ancestral adaptive immune defense system.

Overview

The first reports about CRISPR repeats in prokaryote genomes came from Japan (Ishino et al. 1987) and the Netherlands (Hermans et al. 1991). This was extended to archaea by Mojica (1993). Subsequently, numerous reports have confirmed the presence of CRISPR arrays in most archaeal and about half of the bacterial genomes. The first clues about the putative function of these singular genome arrangements were published by Mojica (2005) who deciphered that some of the unique spacer sequences matched with bacteriophage genomes. And the presence of a piece of a viral genome

rendered the prokaryotes resistant to the same virus, hence proposing that CRISPR arrays would be part of an adaptive immune defense system. This proposal was confirmed experimentally by Barrangou (2007) where they engineered the CRISPR arrays by adding and removing spacer DNA with fragments of viral genomes, thereby transforming the bacteria into resistant or susceptible to the infection by the same virus, respectively. Soon thereafter, it was discovered that the CRISPR system would also work to fight intruding plasmids. Van der Oost found in 2008 that some small RNA molecules (crRNA, for CRISPR RNA) were guiding the antiviral response. Mojica and other found in 2009 the existence of conserved short DNA sequences next to the target site and named them as PAM (Protospacer Adjacent Motif). In 2010, Moineau integrated the evidences available and demonstrated that antiviral or antiplasmid activities were associated with target DNA cleavage. In 2011, Charpentier identified additional small RNA molecules in CRISPR-Cas systems (tracrRNA, for trans-activating crRNA). Also in 2011, Siksnys reported the first successful transfer of a CRISPR-Cas system between two evolutionary distant organisms: from *Streptococcus thermophilus* to *Escherichia coli*. Finally, in 2012, Charpentier and Doudna described the compounds of the CRISPR-Cas9 system of *Streptococcus pyogenes* and suggested its potential use for editing any genome, a proposal for which they were awarded the Nobel Prize in Chemistry in 2020.

Critical Core Mass (Giant Planet Formation)

Yann Alibert¹ and Ravit Helled²

¹Space Research and Planetary Sciences, Physics Institute, University of Bern, Bern, Switzerland

²Geophysical, Atmospheric and Planetary Sciences, Raymond and Beverly Sackler Faculty of Exact Sciences, Tel Aviv University, Tel Aviv, Israel

Keywords

Planet formation · Core accretion (Model for Giant Planet Formation)

Definition

In the core accretion model for giant planet formation, the critical core mass is the minimum core mass that is required to initiate rapid gas accretion, which leads to the formation of a gaseous planet.

Gas accretion begins after the protoplanet has reached (planetesimal/pebble) isolation mass.

Crust

Nicholas Arndt
ISTerre, University Grenoble Alpes, Grenoble,
France

Definition

The crust is the outer rocky layer of the Earth or any other telluric or “rocky” planet or moon. The Earth’s crust has a relatively low density and floats on the underlying mantle. Oceanic crust, which covers about two thirds of the Earth’s surface, is 6–9-km thick and composed mainly of basalt, thus its older acronym identifying the main chemical composition, SIMA for silicate magnesium. Continental crust is thicker (about 10 km thick in rifted portions and >80 km thick beneath active mountain belts), averaging about 30 km. Continental crust is composed mainly of granitic-andesitic and metamorphic rocks, thus the older acronym SIAL for silicate aluminum. Oceanic crust forms at the mid-ocean ridges and is never older than 200 Ma. Continental crust has formed continuously throughout the Earth’s history, from 3.8 or even 4.3 Ga. Mars and probably Venus have basaltic crusts. The lunar crust is basaltic in maria and composed of anorthositic breccia in lunar highlands.

Cryosphere

Nicholas Arndt
ISTerre, University Grenoble Alpes, Grenoble,
France

Definition

The cryosphere is that part of the Earth and of other planets or moons in which temperatures are low and water is solid (ice). On Earth, it constitutes the polar ice caps and pack ice, mountain glaciers, cold deserts, and regions of permafrost which make from 7–17% of the surface of our planet. During the time of near-global glaciations in the Neoproterozoic – the so-called Snowball Earth – the cryosphere encompassed almost all the planet, as is the case at present time for icy moons such as Europa, Callisto, or Ganymede.

Cryostat

Inge Loes ten Kate
Department of Earth Sciences, Utrecht University,
Utrecht, Netherlands

Synonyms

[Cryocooler](#); [Dewar flask](#)

Definition

A cryostat is an apparatus used to maintain very low (“cryogenic” $< \sim 100$ K) temperatures. It typically consists of two vessels, one mounted inside of the other. The inner vessel contains the cold sample (cryogen) mounted inside an evacuated outer vessel. The vessels are held together by a material with low thermal conductivity. The vacuum in the outer vessel serves as a thermal insulator. The two vessels are separated by a radiation shield to prevent heat transfer. The radiation shield is cooled by a cryocooler.

In medicine, a cryostat is a device to cut histological slides, consisting of a microtome (ultrathin slicer) in a freezer. In astrobiology, cryostats are used to generate low temperature conditions, for example, for simulating surfaces of icy moons or Titan or even the surface of Mars. Furthermore, studies of ices and chemistry taking place in ices require the use of a cryostat; examples of these are interstellar and cometary ices.

Cryovolcanism

Therese Encrenaz
LESIA, Observatoire de Paris, PSL, CNRS,
Sorbonne University, University Paris-Diderot,
Meudon, France

Definition

Cryovolcanism is a volcanic phenomenon that occurs in environments with extremely low temperatures. There, instead of molten silicates, cryovolcanoes erupt liquid water, methane, ammonia, or sulfur dioxide onto the icy surface of a planet or satellite. It has been observed on several satellites of the outer solar system. In

particular, active cryovolcanism has been discovered at the surface of Jupiter’s Galilean satellite Europa and on Saturn’s satellites Enceladus and possibly Titan. Traces of cryovolcanism are also found on Triton and possibly Pluto. The ejection products of cryovolcanism include water (H_2O), methane (CH_4), ammonia (NH_3), and dinitrogen (N_2). Cryovolcanism could also be present on other outer satellites and trans-Neptunian objects.

Cryptoendolithic

Felipe Gomez
Centro de Astrobiología (CSIC/INTA), Instituto
Nacional de Técnica Aeroespacial, Madrid, Spain

Definition

Cryptoendolithic refers to one of the three subclasses in which ► [endolithic](#) microorganisms are classified. Cryptoendolithic microorganisms are those able to colonize the empty spaces or pores inside a rock with the connotation of being hidden. This connotation is important to astrobiology as these protected environments inside rocks are putative habitable niches where life could be sustained in very adverse conditions or space environments. Cryptoendolithic microorganisms can survive on inorganic metabolites from the surroundings; thus, these microbes are mainly lithotrophs. Depending on the physicochemical properties of the mineral structure of the rock, it can provide protection against damaging radiation. Some reported examples have been described in basaltic rocks from Antarctica where low temperatures are very restrictive for life or from high-altitude environments with high radiation doses.

CSA

Michel Viso
Innovaxiom, Paris, CX, France

Definition

The Canadian Space Agency was established in 1989 and is committed to lead the development and application of space knowledge for the benefit of Canadians and humanity. Canada began space activities at the early stage of the space era, through an agreement with the US National Aeronautic and Space Administration (► [NASA](#)) to build and launch satellites to study the upper atmosphere. For several years from 1958, Canada operated jointly with the USA, the Fort Churchill base in Manitoba, to launch sounding rockets. In 1969, the federal government created Telesat Canada to build and exploit Canadian communication satellites. The government also set up a Department of Communications that immediately took over from the Communications Research Centre and the Interdepartmental Committee on Space. In 1974, NASA awarded Canada the responsibility of designing, developing, and building the Shuttle Remote Manipulator System (SRMS) for the Space Shuttle. This agreement resulted in Canadarm, the shuttle's 15-m robotic arm, and led to the flight, in 1984, of the first Canadian astronaut (Marc Garneau). In 1979, Canada became an associate member of the European Space Agency (ESA), and in 1985, Canada accepted to participate in the ► [International](#)

[Space Station](#) program. Canadian scientists are cooperating worldwide in manned space flight, space sciences, and exploration of the solar system. For astrobiology, Canada offers also several sites that could be studied or used as Martian analogues.

Canada is pursuing a strategy to develop its expertise in remote sensing, space robotics, and space telecommunication.

In 2010, the CSA employed around 700 full-time equivalents.

Curation Facilities and Sample Receiving Facilities

Sara Russell
Natural History Museum, London, UK

Keywords

Curation · Planetary protection · Contamination · Sample science · Sample return missions

Acronyms

SRF Sample Receiving Facility

Definition

Sample Return Curation is the characterization, digitization, cataloguing, distribution, and especially long-term secure care of samples returned from space.

A Sample Receiving Facility is used to receive samples that require biocontainment

due to the potential presence of extant extraterrestrial organisms.

History

Extraterrestrial sample curation began with the curation of meteorites at museums, first in Vienna and London in the 1700s, and then at other museums and universities in Europe and across the world. The first curation facilities for samples returned from space missions were developed in the USA and Russia in the late 1960s and 1970s to curate rocks and regolith returned from the Moon during the Apollo and Luna missions. Lessons learned at these facilities have been used to inform curation at facilities that have subsequently been established, or are planned, in Japan, China, and Europe.

Overview

Sample return missions are essential to answer many important questions in space sciences. High-precision geochemical measurements, for example, high-precision isotope measurements required for radiogenic age determinations, and the analysis and identification of complex organic molecules and some potential biomarkers, require the presence of a sample in a laboratory on Earth. The two overriding requirements for curation are that the sample is contained in a way that does not expose the Earth to any risk, and that the samples are kept in pristine form, with minimal chemical or biological contamination or reaction with the atmosphere or the terrestrial environment.

Curation of returned samples begins at the moment the return capsule touches down on the terrestrial ground, which may be at a large distance from the planned primary curation facility. A temporary and portable receiving facility may be established in proximity to the return site for use as a base for the sample recovery, for inspection and packaging, and for salvage operations if the return is non-nominal.

“Restricted” space missions, for which the returned samples have not been proved to be

nonhazardous (for example, returned from the surface of Mars), will require transportation to a Sample Receiving Facility (SRF) for preliminary assessment and characterization. Samples will be held in biocontainment until they have been determined not to contain biohazards or until they are made safe by sterilization. Therefore, measurements that are sensitive to sterilization or which are particularly time sensitive must be performed prior to removal from biocontainment. Crewed missions returning from visits to planets considered as potential hosts to pathogens will additionally involve quarantine of astronauts at a suitable facility.

The preliminary examination phase provides a first look at the sample, and initial characterization that will enable subsequent measurements to be made. First, prebasic characterization is undertaken on the unopened sample capsules. This may involve analysis of dust adhering to the capsule and potentially any nondestructive measurements that can be undertaken through the sealed capsule. Next, the sample will be opened and basic characterization takes place including analysis of gas trapped in the dead spaces, weighing, and imaging. Preliminary analysis may then be undertaken on a subsample of the complete returned material. This will include basic chemical, mineralogical, and petrological tests and the databasing of information on individual grains. This cataloguing is essential for future decisions about further analysis both within the facility and externally. After preliminary characterization and biohazard assessment and resolution, the samples can be moved (if required) to their more permanent curation facility/facilities for further work and long-term storage in a physically secure environment.

Sample curation facilities require stringent contamination control to minimize the effect on the returned samples of the conditions on Earth. This will necessitate a strictly controlled temperature and atmosphere, clean (dust-free) conditions, and carefully selected composition of containers and manipulation tools. Robotic manipulation may become increasingly important to minimize contamination by human handling. The exact conditions of the curatorial storage will

depend on the scientific requirements and objectives. The appropriate curation of samples will also depend on the specific nature and condition of the material on the celestial body of origin. For example, future facilities may be required to store samples cryogenically and also provide storage for returned fluids. As well as contamination control, an important aspect of the function of the curation facility is contamination knowledge. Quantifying the degree of inevitable interaction of the specimens with their surroundings is essential. This can be evaluated by the use of witness plates (an object used to monitor the environmental effects experienced by a sample by exposure to the same conditions) and routine analysis of stored samples.

Any curation facility will require a suite of analytical instruments in order to record and characterize the samples and for contamination knowledge. Among typical instruments will be those for making non- or minimally destructive analyses, such as optical and electron microscopes, spectral instruments, and X-ray instruments such as X-Ray Diffraction (XRD) and Computed Tomography (CT).

A fundamental role of the curation facility is to provide effective and stable long-term storage and preservation for research by future generations and as a resource for public engagement. It is imperative that a proportion of any samples returned is kept pristine for decades or centuries to come. This requires curation facilities to have a long-term (decades +) plan for its continued operation and upkeep to a suitable standard to protect the samples. This will enable the returned samples to become a lasting legacy of human exploration of the worlds beyond Earth.

Cuvier's Conception of Origins of Life

Stéphane Tirard

Faculté des Sciences et des Techniques de Nantes,
Centre François Viète d'Histoire des Sciences et
des Techniques EA 1161, Nantes, France

History

The French naturalist Georges Cuvier (1769–1832) was one of the most important comparative anatomists and paleontologists of the beginning of the nineteenth century. Concerning history of life, Cuvier claimed a form of fixism explaining

changes of species during geological time. He imagined several disasters during which certain species would disappear and after which new species would come from other places. During the first part of the nineteenth century, his proposal had a very significant place in biology and paleontology.

Cyanoacetylene

José Cernicharo Quintanilla
Laboratory of Molecular Astrophysics,
IFF-CSIC, Madrid, Spain

Synonyms

CA

Definition

Cyanoacetylene, HC_3N ($\text{H}-\text{C}\equiv\text{C}-\text{C}\equiv\text{N}$), is an organic molecule that is the simplest cyanopolyne ($\text{H}(-\text{C}\equiv\text{C})_n-\text{C}\equiv\text{N}$). It was one of the first molecules detected in space using radio astronomical techniques (Turner 1971). The observation of its rotational lines is used in radio astronomy to derive the physical conditions of interstellar and circumstellar clouds. It is also an important component of Titan's atmosphere (Kunde et al. 1981), where it is found in the gas phase in the upper atmosphere and in ice form in the lower stratosphere (see, e.g., Anderson et al. 2010). It is a trace constituent in cometary atmospheres (comae). Cyanoacetylene has been proposed as a prebiotic reagent for the formation of pyrimidine bases, nucleosides, and nucleotides (Sanchez and Orgel 1970; Powner et al. 2009).

Definition

Cyanobacteria are photosynthetic ► **bacteria** that use ► **water** as reducing power to release

O₂. They evolved early in Earth's history. As bacterial primary producers, cyanobacteria occupy a privileged position among organisms due to their role in the carbon and nitrogen cycles. They are widely adapted to different extreme environments and play an important role, especially in cold polar and alpine environments, because of their tolerance of a wide temperature range, ► [desiccation](#), freeze-melt, and salinity stress.

Overview

Cyanobacteria are oxygenic photosynthetic prokaryotes responsible for the transformation of a reduced atmosphere to an oxidized one. The oxygen produced by this photosynthetic group of bacteria drove life to adapt to the newly formed aerobic environments, resulting in the evolution of novel physiologies, biochemistries, and morphologies. In addition, cyanobacteria, as the photosynthetic partner in the primary endosymbiotic event, introduced photoautotrophy to eukaryotes. The geopaleological record indicates that cyanobacterial ► [photosynthesis](#) took place early in our planet's history. As primary producers, cyanobacteria occupy a privileged position among organisms because of their role in carbon and nitrogen (N-fixers) biological cycles (Whitton and Potts 2000; Knoll 2008; Swingley et al. 2008).

In comparison with other groups of bacteria, cyanobacteria exhibit an unusually wide range of morphologies. Traditional taxonomic cyanobacterial classification is based on morphology and development, recognizing five principal groups: Group I, *Chroococcales*, solitary and colonial unicellular forms; Group II, *Pleurocapsales*, unicellular to pseudo-filamentous, with cells capable of multiple and binary fission; Group III, *Oscillatoriales*, filamentous forms with ► [cell](#) differentiation; Group IV, *Nostocales*, filamentous with cell differentiation to produce akinetes and heterocysts; and finally Group V, *Stigonematales*, with cell differentiation and complex multicellular organization (Komárek and Anagnostidis 1998, 2005). Results of the

application of recent molecular techniques (e.g., sequence of the 16 S rRNA gene) support some but not all these groups. Features like cell differentiation or multiple fissions are supported by molecular analyses, whereas unicellular forms and simple filaments do not generate monophyletic groups. It has been possible to reconstruct an evolutionary history of the cyanobacterial groups, establishing a framework for resolving how their metabolic and phenotypic diversity came about (Six et al. 2007).

Probably due to their evolutionary antiquity, cyanobacteria are widely adapted to all extremes related to changes in geological time (Elster et al. 2001). Tolerance of low-oxygen conditions is still widespread among cyanobacteria and free sulfide is tolerated by some strains. In addition, some cyanobacterial strains can use H₂S as a hydrogen donor. They also tolerate high doses of ultraviolet B and C radiation. All these features have been especially important in the early evolution of cyanobacteria.

Many cyanobacteria can develop in extreme environments, at extremely high (geothermal springs) and low (Antarctic, Arctic, alpine areas, permafrost) temperatures, in hypersaline (halophiles) and alkaline (alkaliphiles) habitats, under high radiation conditions, desiccation, and toxicity stress, etc. A brief survey follows the occurrence of cyanobacteria in different extreme environments.

Thermophilic Cyanobacteria

Results of recent molecular biological studies provide new information about cyanobacteria that inhabit high-temperature habitats. A number of earlier reports proposed that thermophilic cyanobacteria had branched out at the beginning of their evolution. However, recent studies have brought arguments for a later emergence of thermophilic cyanobacteria. The present analyses (Ward and Castenholz 2000) strongly confirm two distinct thermophilic lineages. Geothermal springs can be considered as isolated islands and therefore an ideal site for the origin and evolution of endemic species. Some species of *Thermosynechococcus* spp. are clearly restricted in geographical distribution, although other

thermophilic cyanobacteria, such as *Mastigocladus laminosus* and *Cyanothece minervae*, appear to be cosmopolitan.

Cyanobacteria occupying geothermal springs are not observed below ►pH 4, and their diversity is quite restricted at pH below 6. Temperature, in combination with availability of nitrogen and the presence of free sulfide, determines the cyanobacterial species composition, because sulfide is an efficient inhibitor of oxygenic photosynthesis. The detected upper-temperature limit for cyanobacteria (*Synechococcus lividus*) and for global photosynthesis is presently 73–74 °C.

Cyanobacteria Under Low Temperature, Desiccation, and Salinity Stress

Cyanobacteria, frequently considered warm-water organisms, play an important role in the carbon and nitrogen cycles in cold polar and alpine environments. The ecophysiological features that predetermine their dominance in these environments include: slow growth rate over a wide temperature range, tolerance to desiccation, freeze-melt and salinity stress, and a variety of photoacclimation strategies to both high and low solar irradiance. In cold environments, where invertebrate grazing pressure is limited, the large standing stocks of cyanobacterial biomass are the result of its gradual accumulation over many seasons (Vincent 2000).

At present, endemism of polar and alpine cyanobacteria is under discussion. Castenholz (1992) noted that due to the slow rates of speciation and high dispersal abilities together with the relatively young age of most polar ice-free areas, cyanobacterial endemism in extremely cold environment is improbable. However, recent studies based on 16S rDNA and 16S–23S rDNA intergenic spacer sequences from the Antarctic and Arctic (Taton et al. 2006; Comte et al. 2007; Komárek et al. 2008; Strunecký et al. 2010, 2012a, b) introduced that for selected cyanobacterial clusters apparently belonging to generic entities, geographical limitation plays a prominent role. The north and south polar regions are remarkably different from each other in their geological histories, biodiversity, energy balance, and transport, yet they share the common

challenges for the life that exists there, the fluctuating extremes of cold, and desiccation stress. The Arctic is a geologically young and open area in which rapid glacial and periglacial processes occur. There is a relatively (to Antarctica) higher level of biodiversity and a greater capacity for geographical genome transfers to take place, aided by biological vectors, land mass continuity, and air and oceanic currents. In contrast, a thick ice sheet covers most of the Antarctic continent, which has been geographically isolated for a very long period of time. As a consequence, glacial and periglacial processes are much slower, and genome exchange and movement, and consequently biodiversity, are more limited in the south polar region of Antarctica (Elster and Benson 2004). It has been tested that cyanobacteria survived Antarctic glaciations directly on site after the Gondwana breakup by using the relaxed and strict molecular clock in the analysis of the 16S rRNA gene (Strunecký et al. 2012a). In the contrary, in the Arctic, molecular studies revealed the similarity of strains from Ellesmere Island, the Canadian Arctic, and Abisko, Sweden, with strains from Svalbard. The rate of biological colonization of the Arctic from southern latitudes is relatively high (Strunecký et al. 2012b).

Most polar and alpine cyanobacterial species tested up to now are rather more psychrotolerant than psychrophilic. Polar cyanobacteria have long doubling times in comparison with psychrophilic eukaryotic ►algae and heterotrophic bacteria.

Diverse evidence indicates that the unsaturation of ►membrane lipids correlates with low-temperature sensitivity, although this is not the only factor that regulates low-temperature resistance in cyanobacteria. The unsaturation apparently protects the photosystem II complex from low-temperature photoinhibition.

Cyanobacteria have several strategies to minimize osmotic and mechanical stresses. They are able to produce mucopolysaccharides (exopolymeric substances), which slow down the flow of liquid water during freeze up and thaw (Vincent 2000). Cyanobacteria also respond to these stresses by producing compatible solutes. Large disaccharide sugars, such as trehalose,

sucrose, and glucosylglycerol, are typical compatible solutes in water-stressed cyanobacteria (Reed et al. 1984). The extreme tolerance of cyanobacteria to desiccation is exemplified by their ability to tolerate very low water potential. *Chroococcus* and *Chroococcidiopsis* can both fix CO₂ at remarkably low water potentials.

Cyanobacteria are an important component of hypersaline ecosystems. Compatible solutes are especially vital for cyanobacterial survival in saline desert evaporate soils when they are under the combined stress of desiccation and hypersaline conditions (Oren 2000). In these habitats, glycine betaine is the most common compatible solute. A wide range of species belonging to different taxonomical groups has been reported to thrive at high salt concentrations (e.g., *Microcoleus chthonoplastes*, *Oscillatoria limnetica*, *Synechocystis* spp.).

Light and UV Radiation

Under natural conditions, cyanobacteria experience light conditions that fluctuate rapidly, frequently reaching suboptimal levels for photosynthesis. Both the intensity and quality of the irradiance can vary dramatically during the day and among habitats. In desert terrestrial environments, irradiance may be very bright and cause photoinhibition or damage to the reaction centers of PSII (photooxidative bleaching). Cyanobacteria can modify the protein composition of PSII at high irradiance, making the PSII reaction centers less susceptible to photoinhibition. Rapid light intensity or quality fluctuations result in rapid photoacclimation processes, such as state transition that can modify the photosynthetic apparatus within minutes. These short-term modifications usually do not need protein synthesis. For example, during the state transitions, the phycobilin antennae migrate between the photosystems to optimize the distribution of incoming radiant ► [energy](#) (Bhaya et al. 2000).

In addition, many cyanobacteria are exposed to environmental conditions where continuous ultraviolet radiation (UVR) plays an important role. UVR can lead to direct photochemical damage and degradation of cellular components or to indirect effects produced by reactive oxygen species.

Cyanobacteria possess four lines of defense against UVR (Vincent 2000): they can avoid UVR injuries by (1) selection of ► [habitat](#) (move to deeper water, live beneath rock surface, or live deep within microbial mats); (2) production of umbrella compounds that filter UVR, such as the black or dark pigment Scytonemin (absorbance at ca. 390 nm) and mycosporine-like amino acids (absorbance at 310–360 nm); (3) production of carotenoids (canthaxanthin, myxoxanthophyll, and related compounds), which protect the cells from the oxidative stress caused by the UVR; and (4) further protection against long-term effects of UVR exposure due to the ability to identify and repair the photochemical damage to DNA or the photosynthetic apparatus (Vincent 2000).

Key Research Findings

Some extreme environments on Earth are used as field analogues of extraterrestrial conditions, allowing the limits of survival of various ► [microorganisms](#) including photosynthetic cyanobacteria to be determined. Since cyanobacteria dominate in the polar regions, they can serve as model organisms for evaluation of survival at low temperatures and other stress factors common to the polar ► [environment](#). In the most extreme Antarctic conditions, cyanobacteria play a determining role in (1) desert communities, including soil crust and ► [epilithic](#) and ► [endolithic](#) species of cold polar deserts, e.g., in Dry Valleys in the Antarctic, where the conditions resemble those of the ► [Mars](#) surface (Friedmann 1982), and (2) benthos of permanently frozen lakes, e.g., Lakes Hoare and Fryxell in the Antarctic, which represent another environment that could occur on Mars (de Pablo et al. 2008). The conditions of permanently ice-covered lakes and seas could also be relevant for ► [Europa](#); however, cyanobacteria are not common components of polar seas.

Simulation of conditions on other planets or during interplanetary transport is another approach to the estimation of limits of survival. *Chroococcidiopsis* sp. is able to survive in Mars-like conditions when it is covered by at least 1 mm

of Mars soil analogue that reduces the incoming ► [UV radiation](#). Due to its resistance, this cyanobacterium was proposed as a pioneer microorganism for Mars terraforming (Friedmann and Ocampo-Friedmann 1995). The resistance of the halotolerant *Synechococcus* to space conditions was evaluated during the BIOPAN-3 mission and the effect of space radiation on primary producers, including cyanobacteria, as part of the EXPOSE-R mission launched on 2008 (Rabbow et al. 2009).

Future Directions

As mentioned, cyanobacteria represent the earliest organisms capable of oxygenic photosynthesis. Together with other non-oxygenic photoautotrophs, such as sulfur bacteria, they provide insight into the origin and evolution of photosynthetic processes and data for the estimation of their possible modifications on planets orbiting stars of different spectral classes (Xiong and Bauer 2002).

Definition

Cyanobacteria are oxygenic phototrophic microorganisms. They belong to the ► [Bacteria](#) domain of life and have a plant-type photosynthetic apparatus. They possess two photosystems, PS-I and PS-II, which are connected in series, and their reaction centers usually contain chlorophyll *a*. Water is used as the electron donor and is split into electrons and oxygen by PS-II. The electrons are transported through an electron transport chain through PS-I and eventually reduce electron carriers. These are mainly used for the fixation of carbon dioxide through the reductive pentose phosphate pathway. Their main light-harvesting pigments are the blue- and red-colored phycobiliproteins.

Overview

Cyanobacteria are a monophyletic but highly diverse group of microorganisms (Rippka et al. 1979). Although they are often called “blue-green algae,” they belong to the domain Bacteria and they lack a nucleus or other cell organelles (Stanier and Cohen-Bazire 1977). The confusion with algae, which belong to the domain Eukarya, is understandable since cyanobacteria possess a plant-type photosynthetic system, with two photosystems, PS-I and PS-II, connected in series. Cyanobacteria use water as the electron donor, which by its splitting results in the evolution of oxygen, and their reaction centers normally contain the plant pigment chlorophyll *a*. Cyanobacteria fix CO₂ through the reductive pentose phosphate pathway (Calvin-Benson-Bassham cycle) with ribulose-1,5-bisphosphate carboxylase/oxygenase (RubisCO) as the CO₂-fixing enzyme. This pathway is also common among phototrophic Eukarya (plants and algae) and other autotrophic bacteria. Cyanobacteria occur in almost any illuminated habitat on Earth, including those characterized by extreme environmental conditions.

It is now well established that the eukaryotic plant cell evolved through an endosymbiotic event during which a cell engulfed a cyanobacterium, which subsequently evolved to become a chloroplast, the photosynthetic factory of plant cells (Raven and Allen 2003). The 16S rRNA genes of the chloroplast cluster phylogenetically with the cyanobacteria. Modern cyanobacteria enter into a large variety of symbioses with microalgae and plants, often providing their hosts with fixed nitrogen (Rai et al. 2000).

Cyanobacteria invented oxygenic photosynthesis and were therefore responsible for the oxygenation of the Earth's atmosphere (Knoll 2003). The first big oxygen event occurred 2.4 billion years ago when the oxygen concentration reached 10% of its present value (GOE: Great Oxygenation Event). Besides this rise in the oxygen level of the atmosphere, there are other geological and geochemical evidences for the presence of cyanobacteria at that time. There are microfossils that resemble modern cyanobacteria since 2.1 Ga,

and there are molecular fossils such as methylhopanoids that are considered to have originated from them since at least 1.6 Ga, perhaps 2.5 Ga. Moreover, phylogenetic evidence also points to the presence of cyanobacteria at that time (e.g., Sanchez-Baracaldo et al. 2005). Recently, several geochemical studies point to “whiffs” of oxygen before the GOE. Other studies have suggested an even earlier origin of cyanobacteria of up to almost 3.5 billion years. This goes back to the earliest evidence of life on Earth. This evidence was based on microfossils interpreted to possess similarity to modern cyanobacteria and stable isotope data suggestive of CO₂ fixation by autotrophic organisms as well as other organic signatures. Although these fossil traces could have been produced by other organisms, perhaps anoxygenic photosynthesizers, there is no doubt that cyanobacteria must have evolved long before free oxygen appeared in the atmosphere. It must have taken some time until the oxygen evolved by the first cyanobacteria had oxidized the massive reducing crust and the euphotic layer of the ocean. Thus, it is likely that the origin of cyanobacteria occurred early in the evolution of life on Earth, earlier than 2.5 Ga.

Obviously, an oxygenic phototrophic organism with two photosystems did not evolve at once (Olson and Blankenship 2004). There is no doubt that the predecessor of the cyanobacteria was an anoxygenic phototrophic organism with one photosystem. However, such organism might have been morphologically indistinguishable from modern cyanobacteria. Some modern cyanobacteria are capable of anoxygenic PS-I-dependent photosynthesis using sulfide as the electron donor.

Although monophyletic, cyanobacteria exhibit an amazing diversity. They differ two orders of magnitude in size from the smallest cyanobacteria measuring ~0.5 µm to the biggest of ~50 µm and from unicellular forms to filamentous species of which the trichomes can be as long as 10 mm. Cyanobacteria are also quite unique since they are among the very few organisms outside the Eukarya that display true cell differentiation. Moreover, the growth of populations of

cyanobacteria may be macroscopic in the form of well-defined structured aggregates.

Cyanobacteria are divided into five large divisions that are supported by the phylogeny of the 16S rRNA gene (Fig. 1). Divisions 1 and 2 are unicellular. Cyanobacteria of Division 1 may divide in one, two, or three planes, resulting in typical morphologies of the aggregates. Division 2 is composed of cyanobacteria that divide by multiple fissions and produce small daughter

cells, called baeocytes. Although considered unicellular, several representatives form more or less regular aggregates or colonies, often surrounded with a structured sheath. Division 3 comprises all filamentous cyanobacteria with solely undifferentiated cells. Also these cyanobacteria may form various forms of more or less structured sheathed colonies and bundles. Divisions 4 and 5 comprise filamentous cyanobacteria that show true cell differentiation. Under nitrogen

starvation, some cells in the filaments differentiate into heterocysts (also called by the more appropriate but less common name heterocytes). Heterocysts have only photosystem I and therefore do not evolve oxygen and do not fix CO₂. For carbon and reducing equivalents, heterocysts depend on their neighboring vegetative cells. Heterocysts are the site of N₂ fixation. The special thick glycolipid cell envelope represents a gas diffusion barrier, limiting the flux of oxygen into the cell, thereby providing an anaerobic environment for the oxygen-sensitive nitrogenase. Many heterocystous cyanobacteria also produce akinetes (Adams and Duggan 1999). These are differentiated cells that have also been termed incorrectly “spores” and serve to enhance survival of the organism under unfavorable conditions. Akinetes are drought and radiation resistant but are not heat resistant like bacterial endospores. Akinetes contain ample amounts of storage compounds, such as glycogen (carbon and energy storage) and cyanophycin (nitrogen storage). Akinetes germinate and form hormogonia, another form of differentiation. Hormogonia may also differentiate from vegetative cells when the organism is exposed to environmental stress. Hormogonia are short, motile trichomes with cells smaller than those of the mature organism and do not possess heterocysts. They serve as a dispersion mechanism for the organism and are also important for entering into symbiotic relationships. The main difference between Divisions 4 and 5 is that the latter shows true branching. This occurs when a cell divides in more than one plane and distinguishes it from apparent branching that may occur in both divisions. Heterocystous cyanobacteria also may form colonies and aggregates.

Cyanobacteria are phototrophs and therefore possess photopigments. The great variety of photopigments of cyanobacteria gives these organisms a plethora of colors and allows them to adapt to a variety of light conditions. The main pigment in the photosynthetic reaction centers is the plant-type chlorophyll a. The main light-harvesting pigments are the phycobiliproteins. These pigments are organized in phycobilisomes that are connected to the photosynthetic thylakoid

membranes (Adir 2005). All phycobilisomes contain allophycocyanin. In addition, phycocyanin (blue) or phycoerythrin (orange to red) or both may be present, rendering the organism a blue-green, orange, red, or brown color. Phycoerythrocyanin is another phycobiliprotein with a reddish color that has a rather limited distribution and occurs only in some heterocystous cyanobacteria. Phycoerythrin comes in two forms, namely with the chromophore phycoerythrobilin (PEB) (red) and phycourobilin (PUB) (orange). Both chromophores can be bound to phycoerythrin in various ratios. Some cyanobacteria are capable of complementary chromatic adaptation (Mullineaux 2001). Depending on the wavelength of light, the amounts of phycocyanin and phycoerythrin will vary, turning cells blue green in red light and red in green light. Another form of more subtle chromatic adaptation occurs when organisms vary the ratio of PEB: PUB as a response to the prevailing underwater light conditions (Everroad et al. 2006).

Prochloron and *Prochlorothrix* are cyanobacteria that lack phycobiliproteins and contain chlorophylls a and b. The oceanic picoplanktonic cyanobacterium *Prochlorococcus* contains the divinyl derivatives of chlorophyll a and b, which are specific for this genus (Scanlan et al. 2009). Some strains contain small amounts of phycoerythrin, but phycobilisomes are lacking, and this pigment does not serve as a light-harvesting pigment in *Prochlorococcus*. Another unusual cyanobacterium is represented by the genus *Acaryochloris* which contains chlorophyll d instead of chlorophyll a and is an adaptation to the specific light conditions in its natural environment.

Cyanobacteria utilize a variety of nitrogen sources (Herrero et al. 2001). Many but not all cyanobacteria are capable of fixing atmospheric dinitrogen (N₂). Nitrogenase, the enzyme complex that reduces N₂ to NH₃, is inactivated by oxygen (Bergman et al. 1997). Therefore, the occurrence of N₂ fixation in the oxygenic cyanobacteria is paradoxical. N₂-fixing cyanobacteria have evolved mechanisms to ensure an anoxic intracellular environment for

nitrogenase. Many cyanobacteria are capable of fixing N_2 only under anaerobic and anoxygenic conditions, a strategy that can be termed avoidance (of oxygen) (Gallon 1992). The most advanced strategy is the differentiation of heterocysts (see above). These cells contain nitrogenase, and the strategy is a temporal separation of oxygenic photosynthesis (in the vegetative cells) and N_2 fixation (in the heterocysts). Many non-heterocystous N_2 -fixing cyanobacteria (filamentous as well as unicellular) exhibit a spatial separation of both incompatible processes by confining the fixation of N_2 to the night (Sherman et al. 1998). The oceanic non-heterocystous species *Trichodesmium* is an enigma as it fixes N_2 exclusively during the daytime. It is hypothesized that this organism employs a combination of spatial and temporal separation of N_2 fixation and oxygenic photosynthesis, i.e., that nitrogenase activity is confined to temporary non-oxygenic photosynthetic cells which have also been termed “diazocytes.”

Cyanobacteria possess a remarkably versatile, flexible, and reactive metabolism. In addition to the typical cyanobacterial metabolisms mentioned above, some cyanobacteria exhibit also efficient anaerobic metabolism. For instance, they can perform anoxygenic photosystem I-dependent photosynthesis during which sulfide is used as the electron donor. Some species do this in concert with oxygenic photosynthesis while others rely only on anoxygenic photosynthesis and CO_2 fixation. Cyanobacteria obviously possess dark metabolism in order to survive and cope with the natural day and night cycle. Under aerobic conditions, the glycogen reserve is respired through the oxidative pentose phosphate cycle (the reverse of the Calvin-Benson-Bassham cycle of CO_2 fixation) using oxygen as the electron acceptor. Under anaerobic conditions, some cyanobacteria are capable of fermenting glycogen via a variety of different pathways, and when available they can use elemental sulfur as electron acceptor (Stal and Moezelaar 1997). In order to tune all these processes to the natural day-night cycle, cyanobacteria are the only Bacteria with a circadian clock, which occurs otherwise only within the Eukarya (Golden 2003).

Cyanobutadiynyl Radical (C₅N)

William M. Irvine
Department of Astronomy,
University of Massachusetts,
Amherst, MA, USA

Synonyms

[Cyanobutadiynyl radical](#)

Chemical Formula

C₅N

Definition

The C₅N radical is found in both the envelopes of carbon stars (evolved stars whose atmospheres contain more carbon than oxygen, the excess carbon presumably produced by helium fusion in the latter stages of the star's life) and in cold, dark

interstellar molecular clouds (typically those that have not been heated by star formation). It is an intermediary in the chemistry of the cyanopolyynes and related molecules (Guelin et al. 1998). The rotational transitions of the cyanobutadiynyl radical are observed by radio astronomers at millimeter wavelengths. The anion of this species, C₅N[−], has also been found in space (Cernicharo et al. 2008).

Cyanoethynyl Radical (C₃N)

William M. Irvine
Department of Astronomy, University of
Massachusetts, Amherst, MA, USA

Synonyms

[C₃N](#)

Definition

The four-atom ► [radical](#) C_3N is found in the gas phase in both interstellar ► [molecular clouds](#) and in the expanding envelopes of evolved carbon-rich stars (evolved stars are those which have completed their main hydrogen fusion stage and are thus nearing the end of their energy-producing lifetimes). C_3N is an intermediary in the chemistry of the ► [cyanopolyynes](#) and related radicals.

History

The presence of C_3N in the envelope of the carbon star IRC + 10216 was announced from the pattern of detected emission lines at millimeter wavelengths by Guelin and Thaddeus (1977), before the frequencies of these transitions had been measured in the laboratory. Friberg et al. (1980) stated that the chain of logic leading to this deduction was “worthy of Hercule Poirot (Christie 1945).” This identification is a particularly good example of the ability of heterodyne (high frequency resolution) astronomical measurements to contribute to fundamental molecular physics.

Cyanogen

Henderson James Cleaves II

Earth-Life Science Institute (ELSI), Tokyo

Institute of Technology, Tokyo, Japan

Blue Marble Space Institute of Science,

Washington, DC, USA

Center for Chemical Evolution, Georgia Institute of Technology, Atlanta, GA, USA

Synonyms

[Carbon nitride](#); [Dicyan](#); [Dicyanogen](#); [Nitriloacetonitrile](#); [Oxalic acid dinitrile](#); [Oxalonitrile](#); [Oxalyl cyanide](#)

Definition

Cyanogen is a compound of formula $(CN)_2$. It is a colorless gas at standard temperature and pressure. A cyanogen molecule consists of two CN groups bonded together at their carbon atoms ($N\equiv C-C\equiv N$). Cyanogen is the anhydride of oxamide. It can be generated from cyanide compounds and solutions of metal salts (such as copper (II) sulfate).

It is also formed when ► [nitrogen](#) and ► [acetylene](#) are acted upon by an electrical discharge.

It is implicated as a possible phosphorylating agent for nucleosides and a possible precursor to cyanates and ureas.

Cyanogen Radical (CN)

William M. Irvine
University of Massachusetts, Amherst, MA, USA

Synonyms

CN; Cyano radical

Definition

The diatomic radical CN, containing carbon and nitrogen, is widely observed in the ► [interstellar medium](#) of the ► [Milky Way](#) and external galaxies. It plays an important role in interstellar chemistry, being an intermediary in the production and destruction of such important species as HCN and HNC. The CN radical is also prominent in the visible wavelength spectra of cometary comae (atmospheres), where it is presumably a photodissociation product of molecules such as HCN that are sublimated from the icy nucleus. Note that the molecule C_2N_2 is also referred to as the cyanogen radical. A chemical compound that contains the CN functional group (carbon triple bonded with nitrogen) is called a cyanide, while an organic compound with this CN group is called a nitrile.

History

Unlike most interstellar molecules, which were discovered by radio astronomical observations, CN was first identified at ultraviolet wavelengths in 1940, and it was one of the first known interstellar molecular species. The fundamental rotational line was observed radio astronomically in 1970 by Jefferts et al.

Acronyms

cNMP

Definition

A cyclic nucleotide monophosphate (cNMP) is a nucleotide containing a cyclic phosphodiester bond between the sugar and the phosphate moiety. As the noncyclic nucleotides, the cyclic form is composed of the sugar, the nucleobase, and the phosphate group. The cyclic phosphodiester bond occurs at 3'-5' (2' deoxy-ribose) or, in alternative, at 3'-5' and 2'-3' (ribose) position of the sugar. They are produced under prebiotic conditions (Schwartz 1997; Yamagata et al. 1991; Schoffstall 1976; Bizzarri et al. 2019). cNMPs are possible intermediates for the formation of RNA oligonucleotides in one-pot conditions without the presence of template (Costanzo et al. 2009; Saladino et al. 2018). The oligomerization of 3'-5' cGMP to ribo-oligomers containing up to 25 nucleotides without pre-activation is reported, both in water and formamide (Costanzo et al. 2011, 2012; Šponer et al. 2016a, b).

Cyclopropenylidene (C₃H₂)

William M. Irvine
University of Massachusetts, Amherst, MA, USA

Synonyms

C₃H₂, c-C₃H₂

Definition

The 3-carbon ring molecule C_3H_2 is classified chemically as a ► [carbene](#) and is highly reactive in the laboratory. It was the first cyclic molecular species detected in interstellar ► [molecular clouds](#). Immediately following its identification at short radio wavelengths, it was discovered to be nearly ubiquitous in the ► [interstellar medium](#) (Matthews and Irvine 1985), and it has subsequently also been found in the envelope of evolved carbon-rich stars (evolved stars are those which have completed their main hydrogen fusion stage and are thus nearing the end of their energy-producing lifetimes). The linear ► [isomer](#) of C_3H_2 is also detected in molecular clouds, but its abundance is typically an order of magnitude lower than that of the cyclic isomer (Cernicharo et al. 1991). In diffuse clouds, the abundance ratio between the linear and the cyclic isomers increases by a factor 10 with respect to that observed in dense molecular clouds (Cernicharo et al. 1999). Both 13-carbon and deuterated isotopic forms of C_3H_2 have been detected astronomically.

History

The laboratory measurement of the frequencies of several C_3H_2 rotational transitions by Thaddeus et al. (1985) proved the identification of emission lines that they had earlier observed astronomically.

Cysteine

Kensei Kobayashi
Yokohama National University, Tokiwadai,
Hodogayaku, Yokohama, Japan

Definition

Cysteine is one of the 20 protein ► [amino acids](#), whose structure is shown in Fig. 1. Its three-letter symbol and one-letter symbol are Cys and C, respectively. Among the protein amino acids, only cysteine and methionine contain a sulfur atom. The side chain of cysteine contains a thiol ($-SH$) group, which is often present in the active site of enzymes. In proteins, two cysteine residues often form a disulfide bond (► [Cystine](#)) which is essential in stabilizing the protein 3D structure. Cysteine has been produced in a variety of prebiotic experiments from reducing gas mixtures but has not been detected in carbonaceous chondrites, possibly due to its instability.

Cytosine

Henderson James Cleaves II
Earth-Life Science Institute (ELSI), Tokyo
Institute of Technology, Tokyo, Japan
Blue Marble Space Institute of Science,
Washington, DC, USA
Georgia Institute of Technology, Center for
Chemical Evolution, Atlanta, GA, USA

Definition

Cytosine (C) is one of the four heterocyclic nitrogenous bases found in DNA (A, T, C, and G) and RNA (A, U, C, and G). It is a pyrimidine with two functional group substituents: an amine at the C⁴ position and a keto group at the C² position. When cytosine is combined with ribose via a glycosidic linkage between its N¹ nitrogen and the C¹ position of the sugar, it forms a nucleoside called cytidine; removal of the 2'OH group of this molecule results in the formation of 2'-deoxycytidine also known as deoxycytidine. In Watson-Crick base pairing in nucleic acids, these derivatives form three hydrogen bonds with guanine.

Cytosine and its derivatives hydrolyze fairly rapidly under physiological conditions to give uracil via deamination, with a half-life of approximately 73 years at 37 °C at pH 7. In biological systems, this relatively rapid loss of structural genetic information is corrected by DNA repair enzymes.

Cytosine has been synthesized under simulated prebiotic conditions from cyanoacetaldehyde

and urea as well as from ► [cyanoacetylene](#) and cyanate. It can also be derived from the deamination of 2,4-diaminopyrimidine, itself derived from the condensation of guanidine with cyanoacetaldehyde.

D/H ratio

► [Deuterium/Hydrogen Ratio](#)

D/L-Ratio

Uwe J. Meierhenrich

Institut de Chimie de Nice (ICN), Université Côte d'Azur, Nice, France

Keywords

Amino acids · Biomolecular asymmetry · Chirality · Homochirality · Sugars

Synonyms

[Enantiomeric ratio](#)

Definition

Chiral molecules such as amino acids and sugars are composed of enantiomers that occur in stereochemical D- or L-configurations or in a mixture of them. The D/L-ratio determines the fraction of a D-enantiomer over the corresponding L-enantiomer. Abiotically synthesized chiral molecules usually have a D/L-ratio of 1, or, in other words, they occur as a racemic mixture, as long as no enantiomerically enriched reactants or catalysts are used, or spontaneous symmetry breaking processes operate. In biology, however, amino acids and sugars show a D/L-ratio that is unequal to 1. The D/L-ratio of amino acids in ► [proteins](#) is nearly zero, whereas the D/L-ratio of ribofuranosyl sugar molecules in ► [DNA](#) is infinite.

Overview

A molecular structure that is non-superimposable with its mirror image is said to be chiral (see ► [chirality](#)). Similar to the right and the left hand, chiral molecules exhibit identical physico-chemical properties such as molecular weight,

size, and color. Corresponding chiral molecules are called enantiomers and their resolution in the laboratory is often challenging. In particular, for chiral amino acids and chiral sugars, the D, L nomenclature is still in use, which distinguishes between right-handed D-amino acids and left-handed L-amino acids or right-handed D-sugars and left-handed L-sugars. The synthesis of amino acids in the laboratory, via the Strecker mechanism or via the Miller-Urey experiment, leads to a racemic mixture of the amino acids with a D/L-ratio of exactly 1. Also, the foremost reaction produces sugar molecules in a racemic ratio, that is, the D/L-ratio equals 1. However, living organisms tend to prefer one conformation of the two possible enantiomers. Proteins are exclusively composed of L-amino acids (Meierhenrich 2008). The sugars occurring in RNA and DNA are exclusively of the D-configuration. The genetic material of biological organisms does not use their mirror-image L-sugar structures; thus, the molecular symmetry in living organisms is broken. Today it remains unknown how biomolecular asymmetry was triggered. Various hypothetical models exist to explain biomolecular asymmetry, among them (a) asymmetric photochemistry and the interaction of racemic organic molecules with circularly polarized light, (b) asymmetric phase transitions involving the precipitation of enantioenriched or enantiopure crystals or asymmetric adsorption processes, or (c) the weak nuclear interaction and the transfer of its inherent asymmetry to chiral organic molecules. The discussion of the validity of these hypotheses is influenced by the detection of D/L-ratios between 0.8 and 1 for different amino acids in various meteorites. Until now, L-enantiomeric excesses of up to 18.5% have been identified in the Murchison meteorite but an ► [amino acid](#) with a D/L-ratio larger than 1 has never been detected.

Dallol Geothermal Area

- [Dallol Geothermal System](#)

Dallol Geothermal System

Gian Gabriele Ori
Int'l Research School of Planetary Sciences,
Pescara, Italy
Ibn Battuta Centre, Université Cadi Ayyad,
Marrakech, Morocco

Keywords

Hydrothermal activity · Sebkhā · Dry lake ·
Archea · Habitability

Synonyms

[Dallol geothermal area](#); [Dallol volcano](#)

Definition

The Dallol geothermal system is located in the northern part of the Danakil Depression, Ethiopia (14° 14' 17" N 40° 17' 50" E, at about 120 m below sea level), and it is believed to be one of the most inhospitable environments on Earth. The area is part of the Afar Depression, a portion of a newly born ocean that hosts extreme

environments in term of physical and chemical conditions. Due to the extreme environmental conditions, Dallol and the surrounding areas are a compelling laboratory where habitability and limit of life can be investigated and compared with other planets.

History

The Northern Danakil is one of the most extreme areas in the World. The area is covered by a large salt flat (sebkhā in Arabic) that forms two dry lakes: Assale to the South of Dallol and Ghebrò to the North. Further South there are several large volcanic fields including the Erta Ale with a famous lava lake at the summit. Clearly, this remote geographical setting has left Danakil largely unexplored until the first half of the twentieth century. The Dallol has been almost unnoticed until potash deposits have been identified and their exploitation has been started (Vinassa de Regny 1938). However, the real scientific interest is relatively recent because it started in the 1970s with a few scattered expeditions, but it is only in the recent year that Dallol attracted geochemical, geophysical, and biological research. In recent time, Dallol has been a site visited by several number of scientists from universities and research centers. The Europlanet Research Infrastructure (a research program in planetary sciences financed by the European Commission) organized several multidisciplinary expeditions with the participation of more than 35 scientists.

Overview

The Dallol is a remarkable relief (40 m high), emerging from the large flat plain produced by evaporitic sedimentation (mostly halite and syl-vite) and water flooding (Cavalazzi et al. 2019; Lopez-Garcia et al. 2020). The current active cone is about 3.5 km in diameter and its summit consists in a sort of a few meters deep crater where the hydrothermal activity is concentrated. This *crater* contains of the entire series of features present in other hot springs produced by the

Dallol Geothermal System, Fig. 1 The main evaporitic basin surrounding Dallol. The red signature shows the vast sabkha plain principally made up of halite. Dark shadows indicate differences in humidity and the presence of fine grained (clay and wind-blown silt). To the east of the Yellow Lake, it is possible to observe the transition from halite flat to gypsum “contaminated” surface. The colors become dark blue and green/yellow. Hydrothermal

emission centers are shown in light blue. This can be compared with the brighter color at the center of Dallol representing active or rather recent hydrothermal activity. The area North of Yellow Lake consists of a polygonal evaporitic sabkha with hydrothermal material emitted by meagre but pervasive emissions. (Image: Principal Component Analysis from the multispectral Sentinel 1 data)

salt precipitation of over-saturated brines such as spring mounds, hot ponds, pools bordered by terraces, fumaroles, geysers exhibiting a large variety of colors in sediment and water. The water present in the Dallol *crater* reaches high temperature up to 112 °C. The water is, also, rather acidic with pH values quite below 1 (0–0.2) and, at places, it reaches values below 0, namely –0.74. The water is associated with gas releases of sulfur dioxide (SO₄), hydrogen chloride (HCl), carbon dioxide (CO₂), and hydrogen sulfide (H₂S).

The hydrothermal activity at the top of the Dallol is matched with a large number of different hot spring activities in the surrounding salt flat. One of the most impressive is the Gaet’ale (named also Yellow Lake) at about 4 km south-east of Dallol. The lake is about 60 m in diameter and contains yellowish bubbling water. The bubbling is due to the emission of CO₂. The water of the lake (containing calcium chloride, CaCl₂, and Magnesium Chloride, MgCl₂) is most saline water in the World reaching a concentration of 43% (Perez and Chebude 2017).

Dallol Geothermal System, Fig. 2 The hydrothermal activity features at the top of Dallol. Water ponds and gas emission chimneys are extensively present in the area. For scale: the chimney in the foreground is 1 m high

Southwest of Dallol at about 2 km apart a number of black domes, named Black Mountains, extrude from the plain and form a remarkable landmark in the landscape. These features are made up of black halite and are hydrothermally active with the formation of bischofite flows. An adjacent lake (Black Lake, 12 m in diameter and about 10 m deep) is acidic (about pH 3) with high temperature ranging around 70 °C. Bischofite and carnalite are common around the lake.

The geobiological setting exhibits extreme variables such as temperature, pH, salinity, sediment/rock composition, degassing mechanisms, and atmospheric pressure. This world of extremes is a compelling laboratory for the definition of the

limits of growth of life and, generally, for habitability. In a polyextreme environment such as the one of Dallol and its adjoining areas, it is possible to investigate the habitability by taking into consideration the multidimensional characteristic of this kind of setting. In fact, the environment is characterized by high atmospheric temperature (average 41.2 °C), high water temperature (up to 112 °C), low water pH (lower than -1), high saltwater content (up to 43%), and high content in water of Magnesium. The result is an arid environment with water and sediments limiting formation and growth of life (see Belilla et al. 2019 for discussion). It is possible that interaction among these limiting variables create several barriers to life. However, two inhibiting mechanisms

Dallol Geothermal System, Fig. 3 The hydrothermal activity features at the top of Dallol. Pools in the foreground are surrounded by terraces marked by the brine borders. Filled (inactive) ponds are present and the brine

deposits verge to an ochre/brown coloration. In the far background, an inactive (abandoned) area is getting altered (oxidation) and loses its bright coloration

are considered important limiting factors: the high chaotropicity and low water activity (a_w) due to high Mg content in brines and the association of hypersalinity and hyperacidity conditions. The water and sediment of Dallol and adjoining area are poor in living forms and their variability in physicochemical conditions strongly control the living factors (Belilla et al. 2019; Moors et al. 2020). The living forms basically consist of

Archea (Gómez et al. 2019; Belilla et al. 2019; Moors et al. 2020), and their occurrence is determined by the complex relationships of the interactions by the different constraints. The Dallol is a remarkable analogue to Mars (Fawdon et al. 2015; Kotopoulou et al. 2019) and probably to other Solar and extra-Solar planetary bodies. The analysis of this polyextreme geological environment is just at the beginning.

Definition

The term dark biosphere encompasses those ecosystems that operate in the absence of sunlight and, therefore, their energy input to supporting life does not depend directly on photosynthesis. In these ecosystems, which include the deep continental and oceanic subsurface, life is mainly supported by the geosphere.

Overview

Dark biosphere, essentially, is the sum of underground ecosystems, both oceanic and continental. Deep subsurface ecosystems are oligotrophic extreme environments characterized by the absence of sunlight and oxygen where, in addition, pressure and temperature increase with depth (Kieft 2016; Escudero et al. 2018). Nonetheless, subterranean environments are full of life. Actually, it has been estimated that up to 90% of Earth’s prokaryotes belong to the dark biosphere (Kallmeyer et al. 2012; Magnabosco et al. 2018). Overall, as available organic matter is uncommon

in subsurface environments, minerals or abiotic processes that release energy from minerals are likely the main drivers of subterranean life.

Despite the fact that dark biosphere has been studied since the early 1920s, it is still not completely clear, however, if the available metabolic energy sources are 100% endogenous or, on the contrary, are partly dependent on products photosynthetically generated on the surface. In 1995, Steven and Mc Kinley described the first putative subsurface ecosystem completely independent of the surface in the Columbia River Basalt Group, where the primary producers were chemolithoautotrophic microorganisms. These ecosystems, which operate in the absence of any influence of photosynthesis, that is, organic matter produced on the surface, and which both electron donors and acceptors are renewed by geological processes, were named SLiMEs (Subsurface Lithoautotrophic Microbial Ecosystem) (Stevens and McKinley 1995; Nealson et al. 2005).

In SLiMEs, as the energy input from the surface is discarded, mineralogy and geochemistry define the availability of nutrients and the source of energy and, therefore, the operating metabolism at a given location and depth (Jones and Bennett 2017; Casar et al. 2020). Actually, some microorganisms are able to carry out external electron transfer, using minerals as direct electron donor or acceptors (Shi et al. 2016) or to dissolve minerals releasing compounds that can be used as substrate and contribute to the production of biomass (Torrentó et al. 2011; Shelobolina et al. 2012; Vera et al. 2013; Edwards et al. 2003). However, the direct or indirect use of minerals as energy source implies that extracellular agents such as nanowires or redox mediators need to be produced, which would increase the necessary energy to thrive in these oligotrophic environments. Therefore, energy released abiotically is crucial to sustaining dark biosphere (Hoehler 2004).

Different studies have shown that hydrogen (H_2) is one of the most abundant gases in subsurface environments. In addition, not only can H_2 be produced abiotically by processes such as water radiolysis or water-rock interaction (Apps and van de Kamp 1993) but also it is widely used as

electron donor by chemolithoautotrophic microorganisms. Thus, it is considered the main source of primary energy in SLiMEs (Stevens and McKinley 1995; Pedersen 1997).

However, not all subsurface locations produce enough H_2 to be considered a significant source of abiotic energy and it has been argued that dark biosphere might depend, partially, on the flow of organic matter and energy from the surface (Parkes et al. 2014). Some examples are petroleum deposits or sedimentary rocks, where the presence of organic matter photosynthetically produced is indisputable (Fredrickson and Balkwill 2006). On the other hand, the presence of pores and fractures in subsurface systems may interconnect surface and subsurface, which may lead to the percolation of organic matter rich water that can contribute in feeding the system (Lopez-Fernandez et al. 2018). In fact, heterotrophy is a widespread metabolism in the subsurface and the heterotrophic community is occasionally more diverse and numerous than the lithoautotrophic one (Breuker et al. 2011; Purkamo et al. 2015; Sanz et al. 2021). In these cases, fermenting and heterotrophic would be the main metabolisms that maintain the functioning of subsurface ecosystems.

Dark Streaks (Mars)

Alessandro Airo
Fachbereich Geowissenschaften, Institut für
Geologische Wissenschaften Tektonik und
Sedimentäre Geologie, Freie Universität Berlin,
Berlin, Germany

Definition

Dark streaks is a general term for temporarily darkened surface patches occurring on various slopes on Mars (e.g., crater walls or dune faces) that display a range of morphologies (e.g.,

conical, linear, or braided). The darkening of the surface is believed to be caused by the removal of the surficial dust cover due to dry grain flow, wetting of the soil, or fluvial activity. Over the course of months and years, the dark coloration fades away, which is presumably the result of the surficial accumulation of bright dust particles and/or drying of the soil.

Darwin's Conception of the Origins of Life

Stéphane Tirard

Centre François Viète d'Histoire des Sciences et des Techniques EA 1161, Faculté des Sciences et des Techniques de Nantes, Nantes, France

Keywords

Evolution · Natural selection · Variation

History

Charles Darwin (1807–1882) is the author of the principal evolutionary theory of the nineteenth century, which founded the most important part of the evolutionary thought of the twentieth century.

The son of a physician, he abandoned his own medical studies in Edinburgh after 2 years and went to Cambridge to study theology. There, he was initiated into botany and geology. In 1831, he embarked on the *Beagle* for a 5-year trip around the world. As the only geologist on board, he had to study the formation of the atoll island; moreover, he did the broad work of a naturalist, studying also animals and plants. He came back to England as an acknowledged geologist. However, he and his family settled in Down, in the south-west of London, where he prepared, for 20 years, a theory about the origin of species. In 1858, when

he received a letter from Wallace, a naturalist living in Malaysia, he decided to publish his book rapidly. *On the Origin of Species by Means of Natural Selection, or the Preservation of Favoured Races in the Struggle for Life* was published in 1859, and it expounded his theory based on the variation and selection of living beings.

In the first issue of his book, Darwin claimed that the tree of life came from a unique and simple ancestor. However, the lack of fossils from the oldest period of Earth led Darwin to be very careful on this topic. In the first edition of his book, he only wrote a few words about the origin of life in the last lines of the last chapter:

There is a grandeur in this view of life, with its several powers, having been originally breathed into a few forms or into one; and that, whilst this planet has gone cycling on according to the fixed law of gravity, from so simple a beginning endless forms most beautiful and most wonderful have been, and are being, evolved.

Doing some concessions on the social context, he changed these lines in the second edition, but he continued to assume that there was a very simple common ancestor to all the living beings.

However, Darwin never published any text about the process of the formation of the first living beings. He explained his position in a letter to his friend, the botanist Joseph Dalton Hooker (1817–1911):

It is often said that all the conditions for the first production of a living organism are now present, which could have been present. But if (and oh what a big if) we could conceive in some warm little pond with all sort of ammonia and phosphoric salts, – light, heat, electricity &c. present, that a protein compound was chemically formed, ready to undergo still more complex changes, at the present day such matter would be instantly devoured, or absorbed, which would not have been the case before living creatures were formed. (Calvin 1969)

In this quote, Darwin underlined several important points directly related to his evolution theory. Firstly, he claimed the possibility of a complexification of matter before the existence of life, and he indicated possible chemical ways. Secondly, he analyzed the particular case of the origin of life and suggested that life itself prevented a new formation of life. Therefore,

according to Darwin, the origin of life was the unique event in the history of life that could not repeat itself.

Daughter Molecule, Comet

Therese Encrenaz
LESIA, Observatoire de Paris – Section de
Meudon, Meudon, France

Definition

A daughter molecule is a molecule produced from the photodissociation of a parent molecule which is directly outgassed from a cometary nucleus. The most abundant parent molecule is H_2O ; its dissociation products are H and OH. Other parent molecules include CO, CO_2 , CH_4 , NH_3 , HCN, H_2CO , and H_2S . Daughter molecules include CN, CS, and CO (which appears to be both a parent and a daughter molecule). Daughter molecules and radicals are mostly detected from their visible and ultraviolet spectra, while parent molecules are better observed with IR and millimeter spectroscopy.

De Duve, Christian

Stéphane Tirard
Centre François Viète d'Histoire des Sciences et
des Techniques EA 1161, Faculté des Sciences et
des Techniques de Nantes, Nantes, France

Christian de Duve was a Belgian medical doctor and biologist. In 1974, he was awarded with the Nobel Prize of medicine and physiology for his work and discoveries of lysosomes and peroxisomes.

Throughout his lifelong career, he develops a rich philosophical thought notably regarding the origin of life, publishing several number of books on that subject. He claimed that chemistry deals with deterministic phenomena and consequently that the origin of life depended on the initial conditions in which it arose. Therefore, he claimed that there are probably numerous cases of life in the universe.

Moreover, he distinguished two sorts of evolution: the horizontal evolution that is responsible of diversity of species and depends of environment and the vertical evolution that is responsible for the increase of complexity of organisms and does not depend of environment. For example, for him, the development of the brain is independent of the environmental conditions. For that reason, de Duve claimed that the emergence of the human species was not so improbable.

De Maillet's Conception of Origins of Life

Stéphane Tirard
Centre François Viète d'Histoire des Sciences et
des Techniques EA 1161, Faculté des Sciences et
des Techniques de Nantes, Nantes, France

History

At the end of the seventeenth century, Benoît de Maillet (1656–1738) wrote a book entitled *Telliamed, ou entretiens d'un philosophe indien*

avec un missionnaire français (La Haye chez Pierre Gosse) and signed under this pseudonym: *Telliamed*. This book was published in 1748 and 1755 after de Maillet's death. It presents an imaginary "entretien" between a missionary and an Indian man, who explains his conception of the world and of life. With this astucious rhetorical form, de Maillet presented his own view through the Indian man's mouth. According to him, life on earth came from a panspermic phenomenon. Life first developed itself in seas and then on continents. Therefore, the Indian man, in fact de Maillet, argues against the religious discourse.

Deamination

Matthew Levy

Michael F. Price Center, Albert Einstein College of Medicine, Bronx, NY, USA

Keywords

Ammonia · Degradation · Hydrolysis

Definition

Deamination describes the loss of an amine group from a molecule.

Overview

Deamination is likely to have played an important role in the availability of the biological building blocks of life. In the case of the nucleobases, the

components of ► [RNA](#) and ► [DNA](#), the dominant decomposition products of their exocyclic amine-bearing bases ► [adenine](#), ► [guanine](#), and ► [cytosine](#) are the deaminated products hypoxanthine, xanthine, and uracil, respectively. A calculation of the half-lives for the rates of decomposition of these bases shows that these compounds are not stable on a geologic timescale at temperatures much above 0 °C. This has led to the suggestion that life would be more likely to evolve under cold conditions, where biologically important material can accumulate, rather than at elevated temperatures such as hydrothermal vents, where they would be rapidly destroyed (Levy and Miller 1998).

Deamination is important for other biomolecules such as amino acids. In particular, the deamination of aspartic acid to fumaric acid and ► [ammonia](#) has been shown to have a half-life of 2.8×10^7 years at 0 °C and 96,000 years at 25 °C (Bada and Miller 1968). Equilibrium measurements for this deamination reaction have previously been utilized to estimate the concentration of ammonium ions on the early Earth (Bada and Miller 1968). Thus, deamination is not just a route to the destruction of biomolecules, but also a potential tool to ascertain conditions in the oceans of the early Earth or other environments.

In biology, one of the most critical deamination reactions is the hydrolysis of cytosine to uracil and ammonia. At neutral pH (~7) and 37 °C, the half-life of cytosine through deamination is 200 years in single-stranded DNA and ~30,000 year in double-stranded DNA (Lindahl and Nyberg 1974; Frederico et al. 1990). Measurements for the rate of deamination of free cytosine are similar, albeit slightly faster than those reported for single-stranded DNA (~60 years at 37 °C; Levy and Miller 1998). This deamination rate is sufficiently fast that biological systems must have evolved repair mechanisms fairly early in their history to prevent the resulting DNA damage.

Debris Disk

Paul Kalas

Astronomy Department, University of California, Berkeley, CA, USA

Institute of Astrophysics, FORTH and the University of Crete, Heraklion, Crete, Greece

Keywords

Extrasolar planetary systems · Interplanetary dust grains

Synonyms

[Planetary debris disks](#); [Protoplanetary disk of second generation](#)

Definition

A debris disk is a flattened distribution of dust surrounding a main sequence star that is continuously replenished by the collisional erosion of asteroids and comets. A debris disk may be present for much of the lifetime of a star, as is evident from the presence of the solar system's zodiacal dust cloud ([► \[Zodiacal Light\]\(#\)](#)).

History

Interplanetary dust particles were first observed as the naked-eye phenomenon of [► \[zodiacal light\]\(#\)](#) in

our own solar system. In 1983, the [► \[Infrared Astronomical Satellite \\(IRAS\\)\]\(#\)](#) began an all-sky imaging survey at 12, 25, 60, and 100 μm . Approximately 15% of bright main sequence stars revealed excess thermal emission, typically at 60 μm , that was attributed to thermal emission from circumstellar dust grains. Stellar coronagraphy and imaging resolved a relatively bright and extended dust *disk* surrounding the nearby A star Beta Pictoris (Smith and Terrile [1984](#)). An excess of infrared emission due to circumstellar dust was called the “Vega phenomenon” because the first IRAS discovery of such emission was made for the bright star Vega (Aumann et al. [1984](#)). The Vega phenomenon was attributed to the same dust replenishment mechanisms that create the zodiacal light – the collisional erosion of comets and asteroids that formed around other stars. The fundamental time-scale argument was that collisions, radiation pressure, and [► \[Poynting-Robertson drag\]\(#\)](#) limit the lifetime of circumstellar dust grains to less than 10^5 years (e.g., around luminous A stars such as Beta Pictoris, Vega, and Fomalhaut, grains smaller than 5–10 μm are ejected by radiation pressure), whereas the ages of the Vega phenomenon stars were all greater than ten million years.

The IRAS mission was succeeded by the launches of the [► \[Infrared Space Observatory\]\(#\)](#) (ISO 1995) and the Spitzer (2003) and Herschel (2009) space telescopes. Spatially resolved imaging was initially most successful at 350–850 μm wavelength from the ground, particularly with the SCUBA instrument on the 15-m James Clerk Maxwell Telescope on Mauna Kea, Hawaii. These data showed that circumstellar dust disks have various asymmetries along radial and azimuthal directions (Holland et al. [1998](#); Greaves et al. [1998](#)). At shorter, 1–10 μm wavelengths, the dust distribution around Beta Pictoris was shown to be asymmetric in the radial and vertical directions (Lagage and Pantin [1994](#); Kalas and Jewitt [1995](#); Burrows et al. [1995](#)). With its starlight suppression using coronagraphy and high angular resolution, the Hubble Space Telescope also produced new discoveries of debris disks seen in optical to near-infrared scattered light (Schneider et al. [1999](#)). These results were the basis of theoretical

investigations on how planetary companions could govern the structure of circumstellar dust disks (Roques et al. 1994; Ozernoy et al. 2000). Planetary companions were subsequently directly imaged around the debris disk stars Fomalhaut (Kalas et al. 2008), HR 8799 (Marois et al. 2008), and Beta Pictoris (Lagrange et al. 2009). Thus, the detection and characterization of debris disks are tightly connected to the search for exoplanets.

Overview

The study of debris disks aims to characterize the evolution of planetary systems with respect to the population of minor bodies such as comets and asteroids. Debris disks are distinct from primordial circumstellar disks that are located in star-forming regions such as Orion and Taurus/Aurigae. Debris disks are typically older than 10 Myrs and contain significantly less gas and total mass than primordial disks, and planets within a debris disk have finished forming and are in the process of evolving their atmospheres and surfaces. An external observer would also find that our planetary system has a debris disk in the inner solar system (zodiacal light and asteroid belt) and the outer solar system (see ► [Kuiper Belt](#)), corresponding to the locations where the collisional erosion of comets and asteroids replenishes interplanetary dust particles. Since the cumulative surface area of a planetary system is dominated by dust grains (the total mass is dominated by the largest planets), debris disks are the easiest component of a planetary system to directly detect in reflected light or thermal emission. One of the most important qualities of debris disks is that the gravitational influence of planets disturbs the overall structure of a disk. Therefore, debris disks can flag a system for the presence of planets long before the planets can be detected by other methods (Kuchner and Holman 2003).

Basic Methodology

The successful detection of solid objects next to bright stars is not only a question of angular

resolution but also one of contrast. Debris disks were first detected using thermal infrared techniques ($>3 \mu\text{m}$) because the contrast between the bright star and the faint disk is less in the infrared than at optical wavelengths: whereas a star has an energy spectrum that peaks in the optical and declines in the infrared, the energy spectrum of dust grains peaks at infrared wavelengths, due to the much cooler temperature of the dust. Therefore, infrared and submillimeter detectors are capable of separating the radiation emitted from the star from the radiation emitted by dust grains. The disadvantage is that since resolving power scales as the ratio of wavelength to telescope diameter, the longer the wavelength used, the larger the telescope required. This limitation has been overcome with ALMA which can achieve angular resolution at (sub)mm wavelengths comparable to optical and near-infrared telescopes.

At optical and near-infrared wavelengths, debris disks are detected by grains reflecting (scattering) light from the star, rather than by the dust's own thermal emission. Scattered light data also probe the polarization of scattered light which is a key diagnostic of grain properties such as size and porosity. Optical and near-infrared observations suppress bright starlight using coronagraphy and post-processing techniques that separate the residual point spread function of the star from the fainter astrophysical scene. Thermal observations at mid-infrared to millimeter wavelengths offer relatively good estimates of grain temperature, radial location, and total mass, with some inferences for grain size and composition. In contrast, scattered light observations give the radial, azimuthal, and vertical distribution of grains, as well as estimates of grain size, composition, and porosity by analyzing wavelength dependence and polarization.

A fundamental parameter in debris disk science is the ratio of the infrared luminosity of the dust relative to the total bolometric luminosity of the host star ($L_{\text{dust}}/L_{\text{star}}$). Since debris disks are optically thin, the fractional infrared luminosity is a measure of total dust mass. For scattered light images, the measured surface brightness as a function of distance from the star is proportional to the radial decrease of grain volume number density.

Other parameters often derived in the literature are the inner and outer radii of a debris disk, the grain temperature, the grain size distribution, and the vertical scale height.

Spectroscopy has been used to infer not only the composition of constituent grains but also their dynamics. Overall, spectra of debris disks reveal grain properties very similar to solar system comets, such as crystalline silicate and olivine emission features, as well as atomic gas such as neutral Fe and Ca^+ .

Another key component of debris disk science is estimating the ages of the host stars in order to understand the evolution of planetary systems. Stellar age indicators such as X-ray emission and the presence of lithium (destroyed as stars age) are particularly robust for the low-mass (late-type) stars. However, since main sequence stars have long departed from the cluster environment in which they formed, the method for physically associating the low-mass stars with the high-mass stars is by analyzing galactic space motions, thereby identifying groups of stars with common velocities, particularly in the azimuthal direction around the galaxy. Data from the ► [Hipparcos](#) mission were central in the identification of stellar “moving groups” or “kinematic groups.”

Key Research Findings

Approximately $15 \pm 5\%$ of stars have detectable debris disks, as suggested by the infrared surveys conducted with the IRAS, the ISO, the ► [Spitzer Space Telescope](#), and the Herschel Space Observatory (Matthews et al. 2014). The stellar age estimates indicate that stars with debris disks happen to be the younger (10–100 Myr) stars in the ► [solar neighborhood](#). For example, the Beta Pictoris moving group has several dozen candidate members (Song et al. 2003), and among these, there are at least four debris disks that have been imaged in scattered light, though with significantly different properties such as mass, suggesting that disk evolution is a stochastic process (Kalas et al. 2007). Several mechanisms have

been proposed to explain the large variations in dust mass, such as stochastic collisions between large ► [planetesimals](#) and dynamical stirring as planets grow and dynamically evolve (Wyatt 2008). Despite a significant variation in debris disk properties at a given stellar age, the general finding is that debris disk dust mass varies approximately inversely with age or with age squared (Zuckerman 2001; Rieke et al. 2005).

Most debris disks have inner clearings of material approximately 10–100 AU in radius (Zuckerman and Song 2004; Kalas et al. 2006; Esposito et al. 2020; Fig. 1). In a few cases, this corresponds to the “ice line,” but in many other cases, the most likely explanation is dynamical clearing by a planetary system. For example, the debris disk surrounding Fomalhaut is a torus of dust beginning 133 AU from the star with a Jupiter-mass planet candidate imaged just 18 AU interior to the belt (Kalas et al. 2008).

In many cases, the far-infrared spectral energy distributions cannot be fit by single components of dust, but often require at least one warm inner component and one cold outer component with temperatures ranging from several hundred Kelvin to approximately 40 K, respectively (Hillenbrand et al. 2008). For example, the Epsilon Eridani debris disk can be separated into five components (Backman et al. 2009), and the HR 8799 disk has three components (a warm grain region interior to the three planets and two colder components exterior to the planets; Su et al. 2009). These results give further evidence that debris disk radial structure is governed by the dynamics of planets, with direct analogies to our own solar system.

Future Research Directions

New advances in instrumentation have substantially increased the number of well-resolved debris disks from optical to (sub)millimeter wavelengths, and some studies have probed the time domain as well. However, current methods to model the scattering and emission of dust grains

Debris Disk, Fig. 1 Twenty-four debris disks detected in polarized scattered light using the Gemini Planet Imager in *H*-band with a coronagraph (Esposito et al. 2020). North is up, east is left, and all panels have the same angular size (2.5 arcsec on a side). Nearly all have inner clearings 10–100 au in radius consistent with planet formation;

much like the inner edge of our Kuiper Belt is determined by the orbit of Neptune. With ages between 10 and 100 Myr, these systems are gas-poor, planet formation has finished, and the systems are dynamically evolving toward their final, stable, planetary architectures

struggle to simultaneously fit multiwavelength data for a given debris disk. Future work is needed to improve grain models, such as by simulating porous and fluffy aggregates that blend the physics of both small and large grains. On the observational front, the James Webb Space Telescope will provide unique images and spectra of debris disks in the mid-infrared that could discriminate between icy and refractory grain compositions. Large ground-based telescopes will have their adaptive optics systems and instrumentation upgraded to improve image fidelity closer to each star, ultimately increasing the number of cases where a planet is directly imaged interior to a debris disk. Multi-epoch imaging of already known and new exoplanets will more tightly constrain their orbit elements, offering a clearer

picture of how planets and disks coevolve. Reimaging of debris disks over time will test for time-variable phenomena, which have been recently discovered for the nearby AU Mic debris disk (Boccaletti et al. 2018) and remain difficult to explain.

Decarboxylation

Henderson James Cleaves II
Earth-Life Science Institute (ELSI), Tokyo
Institute of Technology, Tokyo, Japan
Blue Marble Space Institute of Science,
Washington, DC, USA
Georgia Institute of Technology, Center for
Chemical Evolution, Atlanta, GA, USA

Definition

Decarboxylation is a chemical reaction in which a carboxyl group (–COOH) is lost from a parent molecule as CO₂. Many carboxylic acids will

decarboxylate under even mild heating, and there are numerous decarboxylation reactions which are important in biochemistry, for example, in the Krebs cycle, and in the biosynthesis of many neurotransmitters such as dopamine and serotonin. It is also one of the important degradation mechanisms of amino acids and fatty acids in the environment.

Decay Constant

Francis Albarède
Laboratoire de Géologie de Lyon, Ecole Normale Supérieure de Lyon, Lyon Cedex 7, France

Definition

The decay constant (symbol, λ and units, s^{-1} or a^{-1}) of a radioactive nuclide is its probability of decay per unit time. The number of parent nuclides P therefore decreases with time t as $dP/P dt = -\lambda$. The energies involved in the binding of protons and neutrons by the nuclear forces are ca. 1,000,000 times stronger than those of the electronic and molecular forces. Decay probabilities and λ s are insensitive not only to temperature and pressure but also to the strength of the bonds in which the radioactive element is held. The decay constant relates to the ► [half-life](#) of the nuclide $T_{1/2}$ through $T_{1/2} = \ln 2/\lambda$.

Deccan Trapps

Nicholas Arndt¹ and Daniele L. Pinti²

¹ISTerre, University Grenoble Alpes, Grenoble, France

²Geotop, Research Centre for the Dynamics of the Earth System, Université du Québec à Montréal, Montréal, QC, Canada

Definition

The Deccan Trapps (or Traps) are a volcanic plateau, or a large igneous province located in west-central India. It is generally believed that the traps formed through melting of a large mantle plume beneath the Indian continent. Deccan Trapps are a thick (500–3000 m) and large (1.5×10^6 km³) sequence of basaltic lava flows that erupted sub-aerially and rapidly onto the Indian continent about 67–64 Ma ago. The release of large amounts of sulfur gases during repeated cycles of volcanic eruptions that stand for at least 400,000 years has been at the center of a long-standing casual-link debate on the end of dinosaurs (Cretaceous-Tertiary or KT mass extinction). It has been suggested that Deccan Trapps volcanic activity triggered the mass extinction, independently or in concomitance with the impact of an asteroid in the Yucatan peninsula (the Chicxulub crater) while others suggest that only the Chicxulub impact triggered the mass extinction (e.g., Schulte et al. 2010; Chiarenza et al. 2020). Richard et al. (2015) suggested even that the Chicxulub impact triggered global ocean floor volcanism contributing to the Deccan Trapps initiation. This casual-link debate is mainly caused by an incomplete geochronological framework of the Deccan Trapps volcanic activity which initiated somewhere around the Chicxulub impact.

Declination

Daniel Rouan
LESIA, Observatoire Paris-Site de Meudon,
Meudon, France

Definition

The declination is one of the two coordinates of the equatorial system of reference, used to locate a celestial object on the sky. It is the one coordinate measuring the angular distance north or south of the celestial equator, along a meridian passing through that object. Declination is measured positively (+) north or negatively (–) south of the celestial equator from 0° to 90°.

Deep Impact

Hervé Cottin
Laboratoire Interuniversitaire des Systèmes
Atmosphériques, Université Paris Est-Créteil,
Créteil, France

Definition

Deep Impact was a (NASA) mission launched on January 12, 2005, made of a space probe with limited instrumentation (optical imaging and infrared spectral mapping) and carrying a 370 kg impactor made mainly of copper. The impactor collided with the nucleus of comet 9P/Tempel on July 4, 2005, with a relative speed around 10 km/s. The observation of the resulting excavation should have allowed to measure inner properties of cometary nuclei. But, the unexpected large amount of dust released by the impact prevented any direct observation of the artificial crater. However, Deep Impact observations returned unprecedented images of a cometary nucleus and information about the nucleus structure and composition. Then, the Deep Impact spacecraft was redirected toward comet 103P/Hartley through an extended mission. The spacecraft keeps its original name of Deep Impact, while the next leg of the mission after the completion of the main objective is called EPOXI. The flyby occurred on November 4, 2010, and returned high-quality pictures of this comet. After a communication failure on August 8, 2013, and several unsuccessful attempts to restore the contact, the spacecraft was declared lost by NASA on September 19, 2013.

D

Deep Impact, Fig. 1 Tempel 1 impact site. This pair of images shows the area affected by the impactor released by NASA's Deep Impact spacecraft. On the *left*, the image from Deep Impact spacecraft shows a dark mound about 50 m in size (inside a *yellow circle* that shows the area hit by the impactor). The image on the *right*, obtained by

NASA's Stardust spacecraft, shows the impactor erased that dark mound and flattened the area. The *outer circle* annotated on the right-hand image shows the outer rim of the crater, and the *inner circle* shows the crater floor. The crater is estimated to be 150 m in diameter. (Credit: NASA/JPL-Caltech/University of Maryland/Cornel)

Follow-Up

In an attempt to see the crater created formerly, NASA rerouted the Stardust-NExT spacecraft which flew over the nucleus of comet 9P/Tempel on February 15, 2011 (Fig. 1).

Definition

The science of deep subsurface microbiology involves the study of non-phototrophic microorganisms, ecosystems, and biogeochemical fluxes and cycles that occur beneath the soil zones, active layers, and lake beds of continents and the seafloor. Deep subsurface ecosystems are distinct from those that inhabit most surface soils or deep ocean environments in that they are primarily hypoxic to anoxic; the estimated microbial cell turnover times are on the order of decades to centuries (Phelps et al. 1994) and the principal energy sources originate from the geosphere (Parkes et al. 2007). Like surface ecosystems, the subsurface ► [bio-sphere](#) appears to control groundwater chemistry, mineral diagenesis, and organic degradation.

Overview

In June 1986, at the Savannah River Plant (SRP), South Carolina, the modern era of subsurface

microbiology was launched with a few hundred thousand dollars from a US Dept. of Energy (DOE), environmental monitoring program, savings from altering well completion designs. From this auspicious beginning, three wells were cored attaining depths of 200 m using chemical and physical tracers designed by Phelps to constrain microbial drilling contamination. Abundant and diverse microbial communities were observed in the subsurface aquifers, as discussed in a special issue of *Geomicrobiology Journal* in 1989. During the decade that followed, a wide range of environments and rock types were cored during seven field campaigns with a variety of fluids and tracers mostly to depths of several 100 m. By piggybacking on petroleum exploration drilling programs, microbial samples representative of their native subsurface environment were recovered from depths as great as 2.7 km for subsurface microbial and biogeochemical investigations. The teams of scientists that organized and executed these campaigns and examined the cores comprised microbiologists, geochemists, geologists, and hydrologists – some well seasoned and others young and ambitious, many from DOE laboratories and equally many from academia, all supported by DOE's Subsurface Science Program (SSP) and led, inspired, and motivated by the program's manager, Frank Wobber. Other groups formed quickly to explore the subsurface for life. Chapelle and Lovley at USGS began examining Atlantic Coastal Plain aquifers at the same time that DOE was working near SRP. In 1986 Whelan's group from WHOI and, later in 1992, Parkes' group from the Univ. of Bristol initiated studies of sub-seafloor sediments. In 1992, Pedersen from Gothenburg Univ. published his first results from a deep, fractured granite aquifer in Sweden. Other groups built upon earlier Russian studies and began examining the fluids associated with petroleum reservoirs. As summarized in Whitman et al. (1998), a substantial fraction of the Earth's living carbon biomass resides beneath the seafloor and soil zones, although just how massive remains uncertain.

Although the Whitman et al. (1998) review was thorough at its time, the uncertainties in

estimated global subsurface biomass remain large, and many subsurface environments had not been sampled and remain to this day unsampled. Studies of the marine deep sub-seafloor biosphere began later than those for terrestrial settings, but they now take the lead despite sampling challenges. Both deep hot, rift basin-related subsurface marine chemoautotrophic ecosystems and the not so hot, sub-seafloor sediments that represent vast, cold heterotrophic ecosystems functioning on old, buried photosynthate have been sampled. With respect to the latter, Lipp et al. (2008) reported a correlation between the biomass and the concentration of organic photosynthate in marine sediments that constrains the global marine subsurface biomass to lower values (Kallmeyer et al. 2012).

The continental deep subsurface biosphere contains what could be termed "warm," $<100\text{ }^{\circ}\text{C}$ ecosystems that are increasingly chemoautotrophic with depth. The rock-water interactions that fuel these continental subsurface ecosystems are not dependent upon localized magmatic heat input, for example, spreading centers or hot spots, but instead are influenced by regional, topographically driven meteoric fluid flow. In the case of the elevated plateaus and mountain ranges groundwater can penetrate to kilometer depths (Colwell et al. 1997). In the lower elevation granitic aquifers of the Fennoscandian Precambrian shield (Pedersen 1997) and Atlantic Coastal Plain aquifers, the regional flow is slower and shallower (Phelps et al. 1994).

Assuming a maximum temperature for life of $120\text{ }^{\circ}\text{C}$, mean annual surface temperatures that can range from -10 to $30\text{ }^{\circ}\text{C}$, and geothermal gradients ranging from 7 to $80\text{ }^{\circ}\text{C}/\text{km}$, the estimated depth to the base of the deep subsurface biosphere ranges from 1 to 20 km (see Zhang et al. 2005).

Metagenomes have been recovered from million-year-old ice (Bidle et al. 2007), tens of millions of years old, kilometers deep, saline fracture water (Chivian et al. 2008), and subseafloor sediment environments where fluid flux is negligible (Biddle et al. 2008; Chivian et al. 2008).

These studies revealed that in order to repair their DNA from radiation damage, subsurface organisms must metabolize extremely slowly without encountering entropic death. One long-term source of renewable chemical energy is radiolysis of water and serpentinization of mafic and ultramafic rock, which provide sustained sources of oxidants and reductants to these terrestrial and marine subsurface chemoautotrophic microbial ecosystems when organic carbon is scarce (Lin et al. 2005; Sherwood Lollar et al. 2014). Finally, subsurface microorganisms, and even the DNA fragments of deceased subsurface microorganisms, may represent a pool of ancient DNA or paleome (Inagaki et al. 2005), and the differences between their gene sequences and those of related surface organisms may be a direct evolutionary record (Lau et al. 2014).

Deep-Sea Microbiology

Daniel Prieur

Université de Bretagne Occidentale (University of Western Brittany), Brest, France

Institut Universitaire Européen de la Mer (IUEM), Technopôle Brest–Iroise, Plouzané, France

Keywords

Archaea · Bacteria · Diversity · Extremophile · Hydrostatic pressure · Metabolic activity · Piezophiles

Definition

The deep-sea corresponds to depths of 1000 m and more. It is a dark (solar light does not penetrate beyond 100 or 200 m) and cold environment (about 2 °C), exposed to elevated hydrostatic pressure. There is no photosynthesis and the sparse deep-sea organisms that inhabit this environment depend on primary production occurring in the euphotic zone. However, in certain areas, such as cold seep areas or hydrothermal vents, fluids enriched with hydrogen sulfide or methane are discharged in deep waters. These chemicals serve as energy sources for symbiotic microorganisms that provide invertebrates (clams, tube

worms, shrimps) with organic matter produced by chemosynthesis.

History

Deep-sea microbiology began with the report of a French microbiologist Certes (1884) that microorganisms existed in waters and sediments collected at 5 km depth. A second start occurred with the pioneer work of US microbiologists C. Zobell and R. Morita in the 1950s. The availability of pressure-retaining sampling devices during the 1960s and 1970s of manned and robotic underwater vehicles renewed deep-sea microbiology, and several dedicated microbiology teams carried out extensive research particularly in the USA, Europe (Germany, France, the UK), and Japan.

Overview

For the early scientists involved in deep-sea microbiology, the first questions concerned the abundance and metabolic activities of bacteria under in situ conditions (cold temperature, oligotrophy, and elevated pressures). The first experiments concluded that abundant (10^6 cells ml⁻¹ of deep water, 10^9 cells g⁻¹ of deep sediment) deep-sea bacteria were not very active under in situ conditions, essentially because of elevated pressures. This view totally changed with the discovery of piezophilic bacteria living in the digestive tracts of deep-sea invertebrates. In the last decades, many piezophilic deep-sea bacteria have been isolated and described: all are heterotrophic, aerobes, or facultative anaerobes and belong to the phylum of ► [Proteobacteria](#). More recently, ► [Archaea](#) also have been reported from molecular studies, and although their abundance is about 10^4 cells ml⁻¹ in the deep layers, almost nothing is known about their physiology and metabolism. The discovery of hydrothermal vents in 1977 has considerably changed our views about deep-sea biology. At vents and cold seeps, animal communities are dense due to their

symbiotic associations with chemolithoautotrophic bacteria that obtain their energy from the oxidation of reduced compounds (hydrogen sulfide, methane) present in emitted fluids and provide invertebrates with this chemosynthetically produced organic matter. Also, various hyperthermophilic Bacteria and Archaea thrive in the black smokers that flow out of deep-sea vents. Among them are the most impressive extremophiles living on Earth, such as the anaerobic archaea *Pyrolobus fumarii*, which grows optimally at 106 °C (maximum 113 °C), or *Pyrococcus yayanosii*, which grows optimally at 95 °C with an optimal pressure of 52 MPa (maximum 120 MPa) and cannot grow under atmospheric pressure. Both organisms resist normally sterilizing conditions in an autoclave: they have survived for more than 24 h at 120 °C and up to 160 MPa for *P. yayanosii*.

During the last 20 years, deep-sea microbiologists have investigated an unexpected ecosystem: the deep biosphere, a term used to describe the enormous bacterial mass in the upper kilometers of the Earth's crust. J. Parkes first reported the existence of living bacterial cells in deep marine sediments, several hundred meters below the seafloor. They were recently reported at a depth of 1600 m in rocks deposited about 110 million years ago. These ecosystems represent the largest habitat for ► [prokaryotes](#) on Earth. Some organisms of the deep biosphere might be totally independent from solar energy (using abiotically produced carbon and energy sources). A parallel might exist between the emergence of the first life and the deepest parts of the biosphere.

Degassing

Francis Albarède

Laboratoire de Géologie de Lyon, Ecole Normale Supérieure de Lyon, Lyon Cedex 7, France

Synonyms

[Outgassing](#)

Definition

The term “degassing” (or outgassing) refers to the process of releasing atmospheric gas present in the mantle or in magmas when its amount exceeds the solubility limit. The distribution of volatile elements, such as carbon dioxide (CO₂) or argon (Ar), between a solid (or a liquid) and a gas, reaches equilibrium when further transfer from one phase to another entails an overall increase of the system energy. Henry's law states that, at equilibrium, the amount of volatile element dissolved is

proportional to its partial pressure in the gas phase at a specific temperature. Outgassing of planetary mantles by volcanic activity is viewed as a major pathway to the formation of secondary atmospheres on telluric planets.

Deimos

Harald Hoffmann
DLR, Institute of Planetary Research, Berlin,
Germany

Definition

Deimos is the outer of the two Martian satellites that were discovered by Asaph Hall in 1877. It is in nearly circular synchronous orbits around ▶ [Mars](#) with an average distance of 23,458 km to the center of the ▶ [planet](#) and an orbital period of 1.26 days (IAU 2006). Deimos has an overall smooth surface and measures $15.0 \times 12.2 \times 10.4$ km; its bulk density is about 1.5 g/cm^3 . The heavily cratered surface indicates an old formation age. Two hypotheses are actually discussed to explain the origin of Deimos: capture of a D-type ▶ [asteroid](#) or reaccretion of Martian ejecta.

Delta, Isotopic

Daniele L. Pinti

Geotop, Research centre for the dynamics of the Earth system, Université du Québec à Montréal, Montréal, QC, Canada

Definition

The delta notation (symbol: δ) expresses the variation of the isotopic ratio “R” of an element (e.g., $^{18}\text{O}/^{16}\text{O}$), relative to the same ratio in a standard “R_{std}” and normalized to this standard ratio, or $(R - R_{\text{std}})/R_{\text{std}}$. The delta notation is usually expressed in per mil (parts per thousand, ‰) and it is obtained by multiplying the previous expression by 10^3 . Even if the delta notation represents the variation of an isotopic ratio of one element, the value after the “ δ ” symbol is usually presented as the isotope at the numerator of the ratio. As an example, the $\delta^{18}\text{O}$ (‰) = $[(^{18}\text{O}/^{16}\text{O})_{\text{sample}} / (^{18}\text{O}/^{16}\text{O})_{\text{std}}] / (^{18}\text{O}/^{16}\text{O})_{\text{std}} \times 1000$. This notation was proposed to express, in a convenient and readable way, the variability of isotopic ratios in natural systems in which the range is in the third to fifth decimal place (McKinney et al. 1950). It also removes the need to report absolute isotope

abundances and replaces them with relative deviations with respect to standards. The delta notation is usually applied to the stable isotopic ratios of elements, including sometimes the noble gases.

Denaturation

Henderson James CleavesII
Earth-Life Science Institute (ELSI), Tokyo
Institute of Technology, Tokyo, Japan
Blue Marble Space Institute of Science,
Washington, DC, USA
Center for Chemical Evolution, Georgia Institute
of Technology, Atlanta, GA, USA

Definition

In biochemistry, denaturation is the process by which ► [proteins](#) or nucleic acids lose their native quaternary, tertiary, and/or secondary structure. Denaturation can be caused by conditions such as strong acid or base, concentrated salt, organic

solvents, or heat. Protein denaturation generally results in the loss of enzymatic activity. Denatured proteins may become insoluble or aggregate.

► [Nucleic acid](#) denaturation results in the separation of hydrogen-bonded complementary regions when the hydrogen bonds between the strands are broken. These bonds may be restored by annealing. Denaturation typically does not result in the breaking of the covalent bonds which hold a ► [polymer](#) together. Denaturation is often reversible in proteins and nucleic acids.

Denitrification

Ricardo Amils
Departamento de Biología Molecular,
Universidad Autónoma de Madrid, Madrid, Spain

Synonyms

[Nitrate reduction](#)

Definition

Denitrification is a microbial ► [anaerobic respiration](#) in which oxidized nitrogen compounds (e.g., NO_3^-) are used as ► [electron acceptors](#), which may ultimately produce molecular nitrogen (N_2) through a series of intermediate gaseous nitrogen oxide products. Inorganic nitrogen compounds are some of the most common electron acceptors used in anaerobic respiration. One of the most common electron acceptors for anaerobic respiration is nitrate, which can be reduced to NO_2^- , N_2O , NO , and N_2 . The process is the main means by which N_2 is formed biologically. Denitrification completes the nitrogen cycle, by

returning N_2 to the atmosphere. The process is performed primarily by heterotrophic bacteria (such as *Pseudomonads*), although autotrophic denitrifiers have also been identified (e.g., *Thiobacillus denitrificans*). Generally, several species of bacteria are involved in the complete ► [reduction](#) of nitrate to molecular nitrogen, and more than one enzymatic pathway has been identified in the reduction process. Denitrification is a widespread transduction system throughout the phylogenetic tree.

Dense Cloud

William M. Irvine
University of Massachusetts, Amherst, MA, USA

Definition

In relation to the ► [interstellar medium](#), the term dense cloud is only vaguely defined. It is sometimes used to refer to that portion of ► [molecular clouds](#) with densities exceeding a few 100 atoms per cubic centimeter. Some authors use dense to refer to “dense cores,” those regions in molecular clouds with densities of 10^5 atoms per cc or greater, where stars may form or are forming. The gas phase of a dense interstellar cloud consists almost entirely of molecular hydrogen (H_2), with an admixture of ► [interstellar dust](#). Since molecular hydrogen lacks an electric dipole moment and hence has no allowed rotational transitions, the gas in dense clouds is usually traced by observing the millimeter-wavelength rotational

transitions of CO, the second most abundant gas phase constituent (typically about 1 part in 10,000 by number, relative to H_2).

Dense Core

Steven W. Stahler
Department of Astronomy, University of
California, Berkeley, CA, USA

Keywords

Star formation

Definition

Dense cores are the smallest and densest types of molecular clouds. They are particularly significant as being the birthplaces of both single and binary stars. A large fraction of dense cores, in fact, already contain young stars. Many of the rest exhibit a slow, inward contraction, which could be the prelude to the full collapse that results in star formation. Both types of dense cores have temperatures near 10 K. They are slowly rotating and appear elliptical when seen in projection onto the sky. In three-dimensional space, they are prolate spheroids or perhaps more complex, triaxial configurations.

Overview

The Milky Way, like other spiral galaxies, contains both stars and more rarefied, interstellar gas. About half the mass of this material is in molecular clouds, so called because they are chiefly made of hydrogen molecules. Molecular clouds have a wide range of sizes and masses. They are not

uniform, but contain nested substructures. The smallest coherent structures, about 0.1 pc in size and with masses a few times the solar value, are known as dense cores. They are of special importance, since they produce new stars. It is now believed that most binary stars are also created within dense cores.

Throughout most of the volume of molecular clouds, the gas has supersonic internal motion. The dynamical pressure associated with this motion helps to support the cloud for long periods of time against the force of self-gravity. The motion within dense cores, however, is subsonic. Thus, these entities are in balance between internal thermal pressure and self-gravity. They also contain a magnetic field, which aids in the support. The temperature of dense cores, like that of all molecular clouds, is very low, roughly 10 K. It is the combination of low temperature and relatively high density that renders dense cores susceptible to collapse and star formation.

Almost half of observed dense cores already enclose young stars. Since the cores contain solid dust grains along with gas, the embedded stars are highly obscured and can only be seen at infrared and longer wavelengths. The majority of dense cores have no internal stars. The bulk properties of these barren cores are similar to those containing stars. However, a high fraction of starless cores are undergoing inward contraction, as seen by Doppler-shifted emission lines from various trace molecules. This motion, which is subsonic, could be the prelude to the eventual collapse that forms a star or binary near the dense core's center.

Dense cores appear to have elliptical contours, when they are mapped in molecular lines. Each ellipse is a projection onto the sky of the objects' true, three-dimensional shape. This true shape has been difficult to ascertain, with some researchers favoring prolate spheroids (stubby cigars) and others more complicated, triaxial configurations. All agree, however, that the dense cores' shapes do not stem from their rotation. The latter has been observed, and the rate is too small to cause significant distortion of the cloud.

Deoxyribonucleic Acid

- [DNA](#)

Deoxyribose

Henderson James Cleaves
Earth-Life Science Institute (ELSI), Tokyo
Institute of Technology, Tokyo, Japan
Blue Marble Space Institute of Science,
Washington, DC, USA
Center for Chemical Evolution, Georgia Institute
of Technology, Atlanta, GA, USA

Definition

Deoxyribose is an aldopentose ($C_5H_{10}O_4$) found in the backbone of DNA. It exists in two stereoisomeric forms, D and L. The isomer used in DNA is the D-form. It is derived biologically from D-ribose by reduction of the C_2 hydroxyl group via a radical mechanism. It is typically found in deoxynucleotides in the pentofuranose form. In DNA, it is linked via the 3' and 5' hydroxyl groups

to connecting phosphate groups. When attached to a nitrogenous base, it becomes part of a deoxynucleoside.

Depyrogenation

Catharine A. Conley
NASA Headquarters, Washington, DC, USA

Definition

A pyrogen is a substance which causes, when in the blood flow of a homeothermic animal, a rise in the body or central temperature. The pyrogens can be synthetic molecules but often are toxins produced by pathogenic bacteria. Depyrogenation is the process of removing these pyrogens from a solution or compound. Depyrogenation has to be performed on containers and reactants to be used for some life detection tests.

Derivatization

Jeffrey Bada
Scripps Institution of Oceanography, La Jolla,
CA, USA

Definition

Derivatization is the process by which an organic compound is reacted with a reagent, or reagents, to yield products suitable for analyses by various techniques. In many cases, the products are either a volatile adduct suitable for analysis by

▶ [gas chromatography](#) (GC) or a highly fluorescent product that can be separated by liquid
▶ [chromatography](#) and detected at very low levels (parts per billion) by its characteristic fluorescence at an optimal excitation wavelength. In the case of carboxylic acids, the reagents are usually alcohols in the presence of catalysts that convert the original molecules into esters for GC analyses. For the GC determination of amino acids, alcohols in the presence of catalysts are used to first convert the carboxyl groups to esters and reagents such as trifluoroacetic anhydride then used to add components to the primary amino groups to prevent their ionization. For the fluorescent analyses of amino acids, several reagents, such as fluorescamine or *ortho*-phthalaldehyde (OPA), are added to the primary amino group producing highly fluorescent products that can be analyzed using high-performance liquid chromatography.

Desiccation

Gerda Horneck
DLR German Aerospace Center, Institute of
Aerospace Medicine, Radiation Biology,
Radiation Biology, Köln, Germany

Keywords

Anhydrobiosis · Cryptobiosis · Desiccation ·
Dehydration · Habitability of Mars · Survival

Synonyms

[Dehydration](#); [Desiccation effects](#)

Definition

Desiccation describes a process which causes loss of liquid water from a solid surface or from a porous medium (soil, food, ecosystems, individual organisms, etc.). This process leads to drying up of the matter. In biology, several organisms have developed strategies to tolerate desiccation imposed on them.

Overview

Water is one of the essentials for all forms of life on the Earth. Dehydration causes severe damage to various cell components: Lipid membranes may change from planar bilayers to cylindrical bilayers, and carbohydrates, proteins, and nucleic acids may undergo amino-carbonyl reactions (Maillard reactions) that result in cross-linking and finally polymerization of the biomolecules (Cox 1991, 1993). These structural changes can give rise to functional changes, such as inhibited or altered enzyme activity, changes in membrane permeability, and alteration of genetic information. The latter change is especially dramatic, because it may lead to cell death or mutagenesis (Munakata et al. 1997).

Certain organisms possess the ability to withstand extreme dryness, such as plants and animals living in arid or periodically arid environments (temporary rivers or ponds), where they may face the challenge of desiccation. In response to such extreme and unfavorable environmental conditions, organisms may resume a cryptobiotic state, which refers to a state of the organism that has no detectable metabolic activity. Anhydrobiosis refers to the state of an organism that survives the loss of (almost) all body water. In highly desiccation-resistant bacterial spores, the water content in the ► [spore](#) core is naturally reduced to 25–45% of their wet weight. As a consequence, proteins are immobile and enzymes inactive during the spore phase (Setlow 1994). This low water content is one of the reasons for the high resistance of bacterial spores to a variety of physical and chemical harmful agents. The bacterium *Deinococcus radiodurans* shows a

high radiation resistance and likewise a high resistance to desiccation. It has been suggested that the high radiation resistance is an evolutionary consequence of an earlier ► [adaptation](#) to prolonged periods of cellular desiccation (Mattimore and Battista 1996).

From the viewpoint of astrobiology, the ► [survival](#) of microorganisms in outer space is of interest, where they are exposed to a complex matrix of parameters, including the extremely dehydrating space vacuum. Space exposure experiments have shown that although a variety of microorganisms are known to be desiccation resistant, not many were able to cope with the mechanical stress of the high vacuum of space. The record of survival in space was reached by *Bacillus subtilis* spores, of which 70–90% survived after 6 years in space vacuum (Horneck et al. 2010).

► [Mars](#) is an important target of astrobiology, where the assessment of its habitability largely depends on the availability of liquid water. Because Mars is cold, but not always, and extremely dry, but perhaps not everywhere, the concept of a special region on Mars was developed as a way to refer to those places where the conditions on Mars might be conducive to microbial growth (Kminek et al. 2010). It was concluded that any region experiencing temperatures $>-25^{\circ}\text{C}$ for a few hours a year and a ► [water activity](#) >0.5 can potentially allow the replication of terrestrial microorganisms. Such special regions on Mars require special ► [planetary protection](#) measures for landers and rovers sent to the surface of Mars (COSPAR Planetary Protection Policy: <http://cosparhq.cnes.fr/Scistr/PPPolicy%2820-July-08%29.pdf>).

In biotechnology, freeze-drying or lyophilization is used as a method of preserving microorganisms or tissue without destroying their physical structure and viability (Morgan and Vesey 2009).

Deuterium

Mark Dörr
University of Southern Denmark, Odense M,
Denmark

Keywords

Hydrogen · Isotope

Synonyms

[Diplogen](#); [Heavy hydrogen](#)

Definition

Deuterium (Symbol: ²H, earlier, D) (from the Greek: δεύτερος (*deúteros*) = “the second”) is

a stable ► [isotope](#) of ► [hydrogen](#) with a relative atomic mass of 2.01410222 mu and a nuclear spin of 1. Mass spectrometry and various scattering experiments reveal two elementary particles in its atomic nucleus, a positively charged proton and an uncharged neutron. These observations gave rise to its name. Other natural isotopes of hydrogen are *Protium* (^1H) (one proton, 1.00782519 mu, nuclear spin $\frac{1}{2}$) and *Tritium* (^3H) (one proton, two neutrons, 3.01610497 mu, nuclear spin $\frac{1}{2}$, radioactive) (Greenwood and Earnshaw 1984). Because of its mass, deuterium is also called “heavy hydrogen.”

History

Deuterium was discovered in 1931 by Harold C. Urey, who received the Nobel Prize in chemistry (1934) for this finding.

Overview

Hydrogen is the most abundant element in the universe (ca. 76% by mass). The average deuterium-to-hydrogen ratio in the universe is estimated to be ca. 20 ppm (Lellouch et al. 2001). Deuterium has a natural abundance in the Earth’s crust of $^2\text{H}/^1\text{H} = 145$ ppm. In the ocean, this ratio is 155.76 ± 0.1 ppm (a ratio of 1 part per approximately 6420 parts) according to the Vienna Standard Mean Ocean Water (VSMOW) (American Society of Limnology and Oceanography Inc 1995). Deuterium abundance in Jupiter’s atmosphere is about 22.5 ppm (ca. 15% of the terrestrial deuterium-to-hydrogen ratio); that of Saturn’s atmosphere is about 17 ppm (Lellouch et al. 2001). The Jupiter ratio presumably reflects the early solar nebular ratio as well as the one present during the early stages of the universe (Lellouch et al. 2001). Most of the deuterium in the universe is believed to have been produced during the nucleosynthesis era of the Big Bang (~ 10 s after t_0), since other

sources, such as rare cluster decays, and occasional absorption of naturally occurring neutrons by hydrogen do not account for the amount presently observed. If the de novo production rate of deuterium is very low, the amount of deuterium in the universe declines steadily since it is consumed in nuclear fusion reactions in stars. These fusion reactions are much faster than the proton-proton reactions that generate deuterium at very high temperatures in stars. Gamma radiation from ordinary nuclear fusion dissociates deuterium into protons and neutrons. Both reaction kinetics and gamma radiation make it improbable that the concentration of deuterium in the interior of the Sun and other stars is higher than the average universal abundance. In the outer solar atmosphere, however, deuterium is present in the same concentration as the one estimated on Jupiter. The natural deuterium abundance seems to be very similar wherever hydrogen is found.

Deuterium occurs in trace amounts naturally as deuterium gas ($^2\text{H}_2 = \text{D}_2$), but most of the deuterium in the universe is bound to a ^1H atom, forming a gas called hydrogen deuteride ($^1\text{H}^2\text{H}$ or HD). Deuterium exchanges rapidly with hydrogen in many compounds, like R-O-D and R-N-D, but slowly in many R-C-D compounds (R denotes a residue). This is the basis of important kinetic and mechanistic measurements in chemical reactions.

Hydrogen isotopic fractionation is very pronounced in cold interstellar clouds, so that the abundance ratio of (e.g.,) DCN/HCN can be much larger than the cosmic D/H ratio. In fact, doubly deuterated and even triply deuterated molecules are observed in the ► [interstellar medium](#), for example, D_2CO and ND_3 .

[D/H ratio](#)

Definition

The deuterium/hydrogen ratio or D/H is the ratio of the hydrogen isotopes of mass 2 (2H or D, deuterium) and mass 1 (1H or protium). This ratio can be expressed as relative excess abundance of deuterium in per mil (‰) units. The reference is the terrestrial oceanic value of 155.5×10^{-6} (V-SMOW or Vienna-Standard Mean Oceanic Water). The ratio is measured in molecules and minerals, such as clays preserved in meteorites and comets. It can also be measured in mare basalts and highland rocks of the Moon, to determine the carrier of water in the Earth-Moon system but this requires correction for nuclear reactions between the solar wind, the galactic cosmic rays, and the lunar surface. The D/H

ratio shows a heliocentric distribution within the Solar system due to $\text{H}_2\text{--H}_2\text{O}$ vapor exchange, with the lowest value measured in the solar wind and giant planets (21×10^{-6}) and the highest in the HCN compounds in comets (2300×10^{-6}).

Overview

The D/H ratio supports a predominantly chondritic origin of terrestrial water and not a local origin in the Inner Solar system. The debate is still ongoing, but will hopefully be resolved in a near future by analyses of samples from Hayabusa 2 and OSIRIS-ReX return missions.

The water molecule has two elements: H and O, each of them having stable isotopes. The oxygen isotopic ratio, $^{18}\text{O}/^{16}\text{O}$ can be easily fractionated by low-temperature geological processes, such as weathering. The terrestrial water composition from oxygen isotopes cannot thus be compared with that of other cosmic reservoirs, such as the Sun, the asteroids, or the comets. Hydrogen is less fractionated by geological processes than oxygen, mainly because silicate rocks are rather dry and terrestrial isotopic variations are relatively small compared to those observed in different cosmic reservoirs. Deloule et al. (1991) estimated an average δD of $-150 \pm 30\%$ vs. V-SMOW for the primitive Earth, 110‰ depleted compared to the present-day bulk Earth ($\delta\text{D} = -43\%$; Lécuyer et al. 1998). These isotopic variations are relatively small when compared to the total isotopic variation in the Solar system, of 3200‰.

The major hydrogen reservoir in the universe is atomic or molecular hydrogen. The isotopic composition of water in several objects of our Solar system, such as comets, chondrites, or planets, shows a systematic enrichment in deuterium (Robert 2001a) due to the reaction $\text{HD} + \text{H}_2\text{O} \rightleftharpoons \text{H}_2 + \text{DHO}$. Models of the Proto Solar Nebula (or PSN) evolution indicate that once they had entered the nebula, interstellar ice grains vaporized, and the D/H ratio of the resulting deuterium-rich water vapor was lowered through isotopic exchange with molecular hydrogen. Water vapor successively condensed into

microscopic icy grains, with decreasing D/H ratios, the closer they were to the Sun. This heliocentric isotopic gradient reflects the fact that the closer to the Sun, the higher the temperature, and the faster the isotopic exchange between water and molecular hydrogen (Robert 2001a).

The D/H heliocentric gradient predicts that the D/H ratio for water condensed at Earth's distance (1 AU) from the Sun should be $\sim 80 \times 10^{-6}$ or $\delta D = -490\%$ depleted compared the global ocean (Fig. 1). The water isotopic composition of the bulk Earth is only slightly depleted compared to the global ocean ($149 \pm 3 \times 10^{-6}$ or $\delta D = -43\%$; Lécuyer et al. 1998) and is very different from the PSN value of $21 \pm 5 \times 10^{-6}$. Giant planets (which have primary atmospheres of solar composition) have D/H ratios ranging from 21 ± 8 to $65 \pm 2 \times 10^{-6}$ (δD from -865% to -580%), while long-period comets from the colder outer space of the Solar System, the Oort cloud, have D/H ratios much higher than bulk Earth (average D/H of $296 \pm 25 \times 10^{-6}$ or

$\delta D = +900\%$; Robert 2001a, b). Conversely, carbonaceous chondrites show an average D/H of $149 \pm 6 \times 10^{-6}$ ($\delta D = -43\%$; data compiled by Pinti (2005)), identical to the bulk Earth (Fig. 1). Antarctic micrometeorites (which have a CM-CR carbonaceous chondrite composition; Kurat et al. 1994) show an average value of $154 \pm 16 \times 10^{-6}$ or $\delta D = -11\%$ (Engrand et al. 1999, data compiled by Pinti 2005; Fig. 1).

The comparison of D/H ratios of water in the terrestrial oceans and meteorites supports the hypothesis that carbonaceous chondrites – likely Vesta family water-rich asteroids from the orbit of Mars-Jupiter – are the main carrier of water on Earth, although they make only 4% of the mass of Earth. Recently Piani et al. (2020) have measured the D/H in enstatite chondrites (EC), which are believed to be the main building material of the Earth, but previously assumed to be too dry for furnishing any water to the planet. Their results showed that up to 0.5 wt.% of water is contained in this class of meteorites against old data indicating

Deuterium/Hydrogen Ratio, Fig. 1 Variation of the D/H ratio in the Solar System. PSN stands for Proto Solar Nebula. BSE stands for Bulk Silicate Earth. Proto-Earth is the expected initial D/H ratio in the region where the Earth formed, based on isotopic exchange models between molecular H and water (Robert 2001a). D/H ratios measured in carbonaceous chondrites (CI-CM and AMM) and

in Enstatite Chondrites (EC) are compared with those measured in two distinct classes of comets, those from the external Oort Cloud and those supposed to have formed within the Jupiter orbit at the beginning of the Solar System (Hartogh et al. 2011; Altwegg et al. 2015). Note that one Jupiter-family comet has a D/H ratio very similar to that of terrestrial oceans (debated) (Hartogh et al. 2011)

less than 0.01 wt.%. The δD ratio of EC meteorites range between -103‰ and -127‰ vs. V-SMOW, less than that of the terrestrial oceans but close to that of the Bulk Silicate Earth (BSE; -130‰ to -75‰ ; Fig. 1), suggesting that EC could be an alternative carrier of water to Earth.

Devon Island

Richard Léveillé

Natural Resource Sciences, McGill University, St. Anne de Bellevue, Québec, Canada

Definition

Devon Island (federal territory of Nunavut) is a large (66,800 km²), uninhabited island of the Canadian Arctic Archipelago. Situated in a polar desert, Devon Island is considered to be an analog to ► [Mars](#) because it is cold, dry, and largely non-vegetated, with a variety of analogous geological and geomorphologic features. These include the well-exposed and preserved Haughton impact crater and associated impact-induced hydrothermal deposits, as well as intracrater paleolake deposits, alteration minerals, valleys and gullies, and polygonal ground. In addition, the biological characteristics (e.g., endolithic and extremophilic microorganisms, little to no vegetation, low nutrients, and organic biomarkers in impacted rocks) are of particular interest to astrobiologists.

Devon Island's Houghton Impact Structure

Gordon R. Osinski

University of Western Ontario, Department of Earth Sciences/Institute for Earth and Space Exploration, London, ON, Canada

Keywords

Impact crater · Impact cratering · Shock metamorphism · Impactites · Hydrothermal alteration · Microbial habitats · Endoliths · Thermophiles · Mars

Definition

A 23-km diameter, 31-million-year-old complex impact structure located on Devon Island in the Canadian Arctic.

History

The Houghton impact structure was first studied during Operation Franklin in the 1950s, where it was interpreted as a salt dome (Greiner et al. 1963), hence the original name Houghton Dome, a term that is still present on topographic maps of the region. It was subsequently confirmed as the product of a meteorite impact event by the discovery of shatter cones (Robertson and Mason 1975) and coesite (Frisch and Thorsteinsson 1978).

Overview

The Houghton impact structure is a well-preserved and well-exposed meteorite impact structure located on Devon Island in the Canadian High Arctic. With an apparent crater diameter of 23 km and a rim (final) crater diameter of 16 km (Osinski and Spray 2005), Houghton is classified as a midsize complex impact structure. This crater formed 31 million years ago (Erickson et al. 2021) when an asteroid or comet, likely between 1 and 2 km in diameter, struck what is now Devon

Island. It possesses a well-defined rim, featuring fault-bounded terraces, remnants of impact ejecta deposits, a well-preserved series of crater-fill impactites, and a subdued central uplift (Osinski et al. 2005b). The exceptional preservation of the Houghton impact structure is due to several factors, including the lack of other regional geological events since its formation, the cold-based glaciation in this part of the Arctic (which led to relatively little erosion), and the present-day polar desert environment. The latter also makes this crater an excellent analogue for Mars (Lee and Osinski 2005).

It has becoming increasingly clear over the past couple of decades that impact events, while initially destructive, also have beneficial effects for microbial life. As summarized in a recent review article (Osinski et al. 2020a), impact events can deliver and/or generate many of the necessary chemical ingredients for life and catalytic substrates, such as clays. They also create several habitats for life, including hydrothermal systems, crater lakes, highly shocked and porous rocks, and impact glasses. Studies of the Houghton impact structure contributed significantly to this realization that impact events are important astrobiological targets that may have played a central role in the origin of life on Earth, and possibly other planetary bodies. Two of the major astrobiological features of Houghton are the impact-generated hydrothermal system and the impact processing of crystalline rocks to create unique endolithic habitats.

Evidence for hydrothermal activity was first documented at Houghton by Osinski et al. (2001). Further studies resulted in the most comprehensive understanding of the 2D distribution of impact-generated hydrothermal alteration for any complex impact structure on Earth (Osinski et al. 2005a), with four distinct settings and styles of hydrothermal mineralization being recognized: (a) calcite and marcasite-dominated vugs and veins within the crater-fill impact melt rocks, with an increase in intensity of alteration toward the base; (b) quartz-cemented breccias in the interior of the central uplift; (c) intense calcite veining around the heavily faulted and fractured outer margin of the central uplift; and (d) mineralized

pipe structures interpreted as fossil hydrothermal vents around the faulted crater rim. Sulfur isotope data on hydrothermal products provides evidence that the hydrothermal system was colonized by thermophilic (heat-loving) microorganisms (Parnell et al. 2010). Other studies have shown that hydrothermal sulfate minerals continue to provide microbial habitats at the present day (Parnell et al. 2004). Izawa et al. (2011) also showed that the weathering of primary hydrothermal deposits and dissolution and reprecipitation of these products also create potential habitats for endolithic microbes.

Cockell et al. (2002) demonstrated that the impact event resulted in the increased porosity and enhanced translucence of Precambrian gneisses, enabling the colonization of a substrate by endolithic microorganisms that before the impact would have been uncolonizable. Subsequent studies explored the relationship of biomass with shock level and found that rocks shocked to pressures between 35 and 60 GPa provide the most ideal habitat for endolithic organisms (Pontefract et al. 2014) and, further, that microbial diversity is tied to the amount of porosity in the target substrate (Pontefract et al. 2016).

Definition

The Dharwar craton is a part of southern India, underlain by Archean rocks, and extending

roughly between the cities of Goa, Hyderabad, Chennai, and Mangalore in Karnataka and Andhra Pradesh states.

Overview

The Dharwar craton is made of orthogneisses and greenstone belts, collectively formed between 3.3 and 2.6 Ga (Chadwick et al. 2000). It acquired its final structure between 2.56 and 2.51 Ga during a tectonic and metamorphic event that overprinted most previous structures and lithologies (Chardon and Jayananda 2008). This event was accompanied by the intrusion of voluminous granitoids (Chardon et al. 2011). Due to differential erosion and/or tilting, different crustal levels are exposed from south (granulite facies) to north (greenschist facies), allowing to reconstruct a three-dimensional section through the late Archean crust.

To the south, the Dharwar craton is cut by younger (Proterozoic) tectonic structures; various granulitic domains rework the Archean crust. It has also been suggested (Collins et al. 2014) that the northwestern corner of the Dharwar craton (Goa area) represents part of western Gondwana which docked in the Neoproterozoic against the Dharwar craton proper. The craton is covered by younger units to the north and east, including Proterozoic sediments of the Cuddapah basin and flood basalts of the Deccan traps (Fig. 1). Fragments of Archean crust are also found in the heavily reworked granulite terrain of Peninsular India, south of the craton (Collins et al. 2014).

The Dharwar craton is traditionally separated into two main geological domains (west and east) with contrasting ages and geological features. The **western Dharwar craton** is dominated by Mesoarchean rocks, including a ca. 3.3–3.0 Ga basement of TTG gneisses (the “Peninsular Gneisses”) and two successions of greenstone belts: an older, ca. 3.3 Ga Sargur Group, and a younger, 3.0–2.7 Ga Dharwar Group unconformably overlying the Peninsular Gneisses (Chadwick et al. 2000 and references therein). It is further intruded by several late Archean, ca. 2.61 Ga, plutons (Jayananda et al. 2006) of potassic granitoids. In contrast, the **eastern**

Dharwar Craton, Fig. 1 (a) Main crustal units forming the Indian shield. (b) Simplified geological map of the Dharwar craton. (Modified after Chardon et al. (2008))

Dharwar craton does contain only rare Mesoarchean remains; it is mostly made of Neoarchean juvenile granitoids that were emplaced ca. 2.55 Ga ago, concomitant with the main deformation phase (Jayananda et al. 2000; Chardon et al. 2002). However, recent fieldwork, mapping, and geochronology allowed to further subdivide the eastern Dharwar craton and identify a third, intervening domain with distinct features (Moyen et al. 2003; Chardon et al. 2011; Jayananda et al. 2019). Greenstone belts of the eastern Dharwar craton are 2.7–2.5 Ga old. The boundary between these domains has been interpreted as a tectonic suture, although it lacks many typical features of modern boundaries such as thrust-and-fold structures, HP/LT metamorphism, or ophiolites, and exemplifies the ambiguity of the Archean geological record.

The Dharwar craton has been pervasively affected by a ca. 2.55–2.51 Ga tectono-metamorphic event, involving (1) the emplacement of large volumes of mostly granitoids in the eastern Dharwar, (2) high-grade (granulite facies) metamorphism in the lower crust now exposed in the southern part of the craton (these granulites either correspond to modified old gneisses or to juvenile magmas emplaced in the lower crust), and (3) deformation represented by E-W bulk shortening of the crust, accommodated by transcurrent shear zones (in the western Dharwar) and sinking of the dense greenstone belts into the lighter gneissic basement (“sagduction”) (Chardon et al. 1996).

The Dharwar craton has been the focus of research for ancient traces of life, particularly in the western Dharwar craton which contains Archean sedimentary rocks, among others several units of banded iron formations (BIFs) (Manikyamba et al. 1993). In BIFs, Orberger et al. (2012) found spherules containing carbonaceous matter which might be derived from ancient microbial activity (Fig. 1). Stromatolites were also described (Sharma and Shukla 2004).

DHMR

J. Andy Spry

SETI Institute, Mountain View, CA, USA

Definition

Dry heat microbial reduction (DHMR) is a process for bioburden reduction. This process involves heating a spacecraft hardware element in an oven for a duration dependent on the set temperature and bioburden reduction required. It was originally developed for terminal sterilization of assembled spacecraft by NASA's Viking Project. In this case, each spacecraft was heated for 50 h at 111.7 °C including warm-up and cool-down periods. DHMR processes are approved by both NASA and ESA for use with spacecraft hardware over specified ranges of temperature and humidity.

Diacetylene (C₄H₂)

William M. Irvine

University of Massachusetts, Amherst, MA, USA

Synonyms

[Butadiyne](#); C₄H₂; HC₄H

Definition

The molecule diacetylene is the simplest polyyne, which is a hydrocarbon with alternating single and triple bonds; thus, diacetylene has the formula HC≡C-C≡CH. Diacetylene is found as a minor component in the atmospheres of the ► [giant planets](#), including Jupiter, Saturn, and Neptune, and in that of Saturn's satellite ► [Titan](#). In addition, it can be present in circumstellar environments, for example, in the envelope of the protoplanetary nebula CRL 618 (Cernicharo et al. [2001](#)).

Diagenesis

Nicholas Arndt

Emeritus Professor, ISTerre, University Grenoble Alpes, Grenoble, France

Definition

Diagenesis refers to all physical-, chemical-, and biological-related processes which bring sediments to be transformed into a ► [sedimentary rock](#) (lithification), exclusive of ► [weathering](#). Transformation of an unconsolidated sediment into solid rock is produced through a combination of compaction, recrystallization, dehydration, mineral replacement, dissolution, and cementation processes. Diagenesis begins when a detrital grain is sedimented and begins its interaction with the pore waters and overburden. Diagenesis ends when these processes grade into metamorphism, and sedimentary textures and structures (such as bedding, grading, bioturbation, etc.) are lost. Diagenetic processes thus take place at temperatures lower than 200 °C and pressures lower than 3 kbar: mostly result in minor to moderate changes in the rock's mineralogy and texture. Commonly, clays, silica minerals, evaporites, or carbonates replace or alter detrital grains, form cement, and fill pore spaces, thereby reducing the porosity and permeability of the rock. Organic carbon is also degraded during diagenesis through the metabolism of various heterotrophic bacteria. Diagenesis is an important process controlling the preservation of morphological, molecular, chemical, and biological signatures of life in older rocks.

Diamictite/Diamicton

Daniele L. Pinti

Geotop, Research Centre for the Dynamics of the Earth System, Université du Québec à Montréal, Montréal, QC, Canada

Synonyms

[Mixtite](#)

Definition

Diamicton is a poorly sorted terrigenous sediment. When lithified to sedimentary rock, it's called diamictite. Diamictite contains a wide range of particle sizes, from gravel to sand, dispersed in a clayey matrix. The nonlithified equivalent of diamictite is diamicton. Diamictite forms primarily in (sub)glacial environments (moraines) and in volcanic environments as *lahars* (debris flow composed of chaotically mixed pyroclastic material, rocky debris, and water). The astrobiological interest in diamictite is due to its possible significance as a climate indicator in suspected glacial sedimentary deposits, thus serving to identify similar processes in Martian polar caps. The fine material in diamictite is subject to rapid outwash during deglaciation. On Earth, it has been invoked to have caused excess alkalinity in the ocean (e.g., Huang et al. 2016) at the end of the Cryogenian global glaciation (20–635 Ma) which is related to a ► [Snowball Earth](#) episode.

Diamino Acid

Uwe J. Meierhenrich

Institut de Chimie de Nice (ICN), Université Côte d'Azur, Nice, France

Keywords

Amino acids · Chirality · Murchison meteorite · Peptide nucleic acids

Synonyms

[Diamino carboxylic acid](#)

Definition

Diamino acids are diamino carboxylic acids. Diamino acids are molecules that contain at least one carboxylic acid group (COOH) and two amine functional groups (NH₂). Diamino acids belong to the chemical family of amino acids. Diamino acids often but not always contain a stereogenic center and can therefore be chiral. The protein ► [amino acid](#) lysine is a diamino acid.

Overview

In biochemistry, diamino acids, that is, amino acids containing a second amine functional group, are of particular interest. Lysine is a protein diamino acid. According to systematic studies on the recruitment order of amino acids and diamino acids in proteins, diamino acids were recruited in a relatively late stage of evolution. Ornithine and 2,6-diaminopimelic acid are nonprotein diamino acids that play important roles in the urea cycle and in bacteria cell walls.

Diamino acids are of particular interest in discussions of chemical evolution and the origin of life on Earth, since they can be used as monomers for the synthesis of peptide nucleic acids (PNAs), which some have suggested may have played a

role in the early evolution of life (Nelson et al 2000). There are numerous possible peptide nucleic acids. One type of PNA molecule is composed of N-aminoethylglycine leading to aegPNA, and others can be constructed from diamino acids (da) leading to daPNA. Peptide nucleic acids such as aegPNA and daPNA are capable of forming duplex structures with individual RNA and DNA strands. PNAs are nucleic acid analogs, and they are considered as candidates for the first genetic material on Earth. In this case, peptide nucleic acids may have transferred their genetic information to RNA and DNA (Meierhenrich 2008).

The diamino acids 2,3-diaminopropionic acid and 2,4-diaminobutanoic acid have been identified both in the Murchison meteorite and in the products of comet simulation experiments (artificial comets) (Munoz Caro et al. 2002; Meinert et al. 2012). PNA oligomers have never been detected in living organisms, in meteorites, or in artificial comets, although some research has suggested these may be prebiotic compounds.

In the context of the origin of biomolecular homochirality, the chiroptical properties of diamino acids have been studied. ► [Circular dichroism](#) spectra of zwitterionic L-diamino acids in solution show maxima at 200 nm (Bredehöft et al. 2007).

Acronyms

DAMN

Definition

A stable intermediate in formamide- and hydrogen-cyanide-based prebiotic syntheses (Saladino et al. 2005; Hudson et al. 2012; Roy et al. 2007), DAMN, a HCN tetramer, forms needle-shaped pale yellow or colorless crystals, whose melting point is at 178–184 °C (Moser et al. 1967; Penfold and Lipscomb 1961). It is synthesized by a condensation from AMN (aminomalonitrile) in basic HCN solutions (Oró and Kimball 1962). In prebiotic synthesis of purines, it undergoes a photochemical interconversion to diaminofurmaronitrile (DAF), and conversion to 5-aminoimidazolecarbonitrile (AICN) or 4-amino-5-cyanoimidazole (ACI) (BECKER et al. 1973; Boulanger et al. 2013). Glycine is produced by its acidic hydrolysis (6 M HCl, 184 °C, 24 hod.); in basic environment it forms peptidic solids (Moser et al. 1968). DAMN is important to plausible prebiotic syntheses initiated by heat (Saladino et al. 2004), UV light (Saladino et al. 2004), or an impact event (Ferus et al. 2015).

History

After Miller experiment producing aminoacids (Miller 1953), the first example of the prebiotic synthesis of purines has reported Oró (Oró 1960) by refluxing a concentrated aqueous solution of ammonia and HCN (1.0–11 M solutions of HCN) for several days to give adenine (Oró 1960). The mechanism of formation of purines from HCN has been then studied in detail. Ferris and Orgel first recognized that AMN and DAMN were important intermediates for these transformations (see [Roy et al. 2007] and references therein).

Diaminovaleric Acid

► Ornithine

Diapirism

Nicholas Arndt

ISTerre, University Grenoble Alpes, Grenoble, France

Definition

Diapirism refers to an upward migration of low-density material, commonly accompanied by a downward migration of denser diapirs nearby. A *diapir* is a teardrop-shaped body of solid but ductile, low-density rock that ascends through denser, more rigid rock. Examples are ice, mud (mud volcanism), and salt diapirs in sedimentary sequences and possibly dome-like intrusions of granitic gneiss in Archean cratons. Diapirism produces a characteristic dome-and-basin structure that may be characteristic of vertical tectonics in hot, ductile Archean continental crust (sagduction). The higher temperature results from the decay of radioactive elements, which were more abundant in the Archean continental crust than today. Salt diapirism is widespread in sedimentary basins that had seen the accumulation of thick evaporitic strata, such as Angola, Morocco, the northern Gulf of Mexico, Southern Iran, Western Kazakhstan, and Northern Germany.

Mud diapirism is observed in regions where overpressure develops in unconsolidated shale-rich strata, such as in pro-delta settings, in sabkhas where it is usually related to groundwater fluctuations, and in hydrocarbon systems. Mud diapirism may occur on Mars's surface and icy diapirism on Saturn's satellites such as Ganymede.

Diastereomers

Jeffrey Bada
Scripps Institution of Oceanography, La Jolla,
CA, USA

Definition

Diastereomers are optically active ► [isomers](#) that are not ► [enantiomers](#). They are characterized by having more than one chiral center. A diastereomer with n chiral centers has 2^n possible ► [stereoisomers](#). Thus, for a diastereomer with two chiral centers, there are four possible stereoisomers: a pair of diastereomers with two pairs of enantiomers. One example is the diastereomers l-isoleucine and d-alloisoleucine. For isoleucine, the enantiomers are l- and d-isoleucine and for alloisoleucine the enantiomers are l- and d-alloisoleucine (see Fig. 3 in ► [Amino Acid](#)).

Diastereomers have different physical properties (different melting points, boiling points, solubilities, etc.). Their chemical properties also differ in that they react with reagents at different rates. Thus, they can be directly separated by chromatographic methods without the need for chiral reagents.

Diazenylium (N_2H^+)

William M. Irvine
University of Massachusetts, Amherst,
MA, USA

Synonyms

N_2H^+

Definition

Protonated molecular nitrogen (protonated ► [dinitrogen](#)), N_2H^+ , is used by radio astronomers and astrochemists as a tracer of dense gas in ► [molecular clouds](#), since its large electric dipole moment requires relatively high densities to collisionally excite the pure rotational transitions at millimeter wavelengths. Since the presumed reservoir of most nitrogen in these clouds, molecular nitrogen (N_2), has no easily accessible transitions, N_2H^+ is an important indicator of the nitrogen chemistry in these regions. It is particularly useful, since it is one of the last gas phase species to freeze out onto the ► [interstellar dust](#) grains at the center of cold clouds.

History

The ion N_2H^+ was identified in interstellar molecular clouds by means of the characteristic hyperfine splitting pattern of the fundamental rotational transition ($J = 1-0$) at 93 GHz (Turner 1974), 2 years before this transition was measured in the laboratory, providing an interesting example of the ability to do fundamental molecular physics experiments in space. The interpretation of the emission from this species in molecular clouds has been recently revived by Daniel et al. (2013).

Dicarboxylic Acid

Henderson James Cleaves II
 Earth-Life Science Institute (ELSI), Tokyo
 Institute of Technology, Tokyo, Japan
 Blue Marble Space Institute of Science,
 Washington, DC, USA
 Center for Chemical Evolution, Georgia Institute
 of Technology, Atlanta, GA, USA

Definition

Dicarboxylic acids are organic compounds containing two ► [carboxylic acid](#) functional groups. Dicarboxylic acids generally show the same chemical behavior and reactivity as monocarboxylic acids. The ionization of the second carboxyl group occurs less readily than the first one, because more energy is required to separate a positive hydrogen ion from the anion than from the neutral molecule.

Dicarboxylic acids are important metabolic products, for example, as Krebs cycle intermediates (e.g., α -ketoglutaric acid, $\text{HOOC}(\text{CH}_2)_2\text{-COCOOH}$) and the products of fatty acid oxidation. The simplest dicarboxylic acid is oxalic acid (HOOC-COOH); others important in biochemistry include malonic ($\text{HOOCCH}_2\text{COOH}$), succinic ($\text{HOOC}(\text{CH}_2)_2\text{COOH}$), and glutaric ($\text{HOOC}(\text{CH}_2)_3\text{COOH}$) acids. The protein ► [amino acids](#), aspartic ($\text{HOOCCH}_2\text{CH}(\text{NH}_2)\text{COOH}$) and glutamic ($\text{HOOC}(\text{CH}_2)_2\text{CH}(\text{NH}_2)\text{COOH}$) acids, are also dicarboxylic acids.

Dichotomy, Planetary

Daniela Tirsch

German Aerospace Center DLR, Institute of
Planetary Research, Berlin, Germany

Synonyms

[Separation](#); [Split](#)

Definition

A dichotomy refers to the splitting of surface and other planetary features in two dissimilar, non-overlapping parts. On [▶ Mars](#), a dichotomy can be found in terms of crater density and topography with the highly cratered southern highlands and the less cratered northern lowlands. A further dichotomy is speculated to exist with respect to crustal thickness. The [▶ crust](#) of the northern lowlands could be much thinner (ca. 32 km) than the crust of the southern highlands (ca. 58 km). This has been derived from an interpretation of the gravity field assuming a constant crust density. The two competing formation hypotheses involve an exogenic cause (e.g., a giant impact) and an endogenic formation mechanism (e.g., degree-1 mantle convection). On the Moon, a dichotomy is known regarding the distribution of [▶ basalt](#), with the near side comprising about 90% whereas the far side only exhibits 10 % of the bulk basalt abundance. The reason for this is again a dichotomy in crustal thickness causing basalt plumes to easily reach the surface on the thinner near side (60 km) in contrast to the thicker far side (120 km). The Earth's hypsometric curve displays another dichotomy in surface elevation between the continents and the ocean basins.

Diderot's Conception of Origins of Life

Stéphane Tirard

Centre François Viète d'Histoire des Sciences et
des Techniques EA 1161, Faculté des Sciences et
des Techniques de Nantes, Nantes, France

History

The French philosopher Denis Diderot (1713–1884) wrote about life in several of his more famous texts, notably in his *Entretiens* (1776) and especially in *Le Rêve de d'Alambert* (from 1769, but published in 1830). Diderot was a partisan of spontaneous generation and of transformation of matter theories. In his *Elements de Physiologie* (published posthumously in 1875), he claimed that nature produced only a few living beings, perhaps only one, of which all the others would come from by combination, micturition, and dissolution and which would vary infinitely.

Differentiation

► Fractionation

Differentiation, Planetary

Frank Sohl¹ and Doris Breuer²

¹Deutsches Zentrum für Luft- und Raumfahrt (DLR), Institut für Planetenforschung, Berlin, Germany

²German Aerospace Center (DLR), Institute of Planetary Research, Berlin, Germany

Keywords

Accretion · Convective overturn · Core formation · Crust segregation · Degassing · Magma ocean · Partial melt

Definition

Planetary differentiation is the separation of different constituents of planetary materials resulting in the formation of distinct compositional layers. Denser material tends to sink into the center and less dense material rises toward the surface. If internal differentiation of a ► [terrestrial planet](#) has run to completion, the interior would be subdivided into an iron-rich metallic core and a silicate ► [mantle](#), overlain by a chemically distinct ► [crust](#) enriched in ► [basalt](#).

Overview

The accretion of the terrestrial bodies from planetesimals provides the initial source of energy for subsequent planetary evolution. The amount of kinetic energy converted to heat during accretion is not well known because it is strongly dependent on specific formation timescales and environmental conditions. Heat sources, other than deposition of impact energy during accretion, are the release of energy through gravitational separation of light and dense constituents, the decay of radioactive heat sources, and additional external heat sources

such as tidal heating (e.g., Schubert et al. 1986; see ► [Tides, Archean](#)). Provided that a sufficient amount of energy was retained during accretion, a near-surface magma ocean would have formed atop of the growing protoplanet. Chemical differentiation of the magma ocean would be affected by impact stirring, convective mixing, cooling, and solidification (e.g., Abe 1993). The solidification timescale of the magma ocean is determined by the balance between the heat flow entering from below, latent heat release upon crystallization, and heat loss at the surface. The crystallization of the magma ocean is thought to cause initial compositional layering in terms of unstable cumulate density stratification, thereby invoking gravitational overturn by convective instability (Elkins-Tanton et al. 2003). This may have led to the formation of an early basaltic crust and chemically distinct mantle reservoirs on terrestrial planets. Aqueous alteration involving chemical reactions between olivine-rich mantle ► [rock](#) and liquid water may have caused the release of a substantial amount of ► [hydrogen](#) (► [Serpentinization](#)). If the energy released by gravitational separation of light and dense constituents were sufficient to invoke melting of the remaining mantle material, the separation process would become energetically self-sustaining and will run to completion within a short period of time (tens of million years). The subdivision of terrestrial planet interiors into crust, mantle, and core (e.g., Sohl and Schubert 2007; see ► [Interior Structure, Planetary](#)) can be attributed to such intense differentiation events, commonly referred to as runaway differentiation.

Basic Methodology

The differentiation and associated chemical evolution of a terrestrial body is in general the consequence of partial melting in its interior. Density differences between the melt and the solid residuum would then result in their separation. For larger planets with increasing accretion time, the melting is caused by impact energy and results in the formation of a magma ocean close to the surface. In a magma ocean, the much denser iron

sinks and accumulates at its base. Iron parcels then settle further to the center of the solid or partly solid planet by Rayleigh-Taylor instability (Stevenson 1990). The larger the accumulated iron diapirs, the higher are the sinking velocities. The gravitational energy released by core formation is converted into thermal energy, which strongly heats the interior. As a consequence, the temperature profile is inverted to decrease from the center toward the surface. The total energy released by the differentiation of a homogeneous planet into an iron-rich core and a silicate mantle can be estimated from the difference between the potential energy stored in a homogeneous planet after accretion and the potential energy of the differentiated, two-layer planet (Schubert et al. 1986). If that amount of energy were distributed homogeneously within the interior, assuming thermal equilibrium between the mantle and the core, the mean temperature would rise about 1000 K for the Earth and about 300 K for Mars (Solomon 1979).

Further chemical differentiation of a planetary mantle is usually associated with crust formation. The process of crust formation can, in general, be divided into two phases: primary and secondary crust formation. A primary crust can be formed as a consequence of freezing of a magma ocean during an early state of planetary evolution. Whereas light minerals like plagioclase feldspar would rise toward the surface forming an anorthositic crust, heavy minerals such as olivine would sink to the bottom of the magma ocean. This gravitationally induced crystal differentiation will result in a chemically layered mantle.

Key Research Findings

The separation of the metal from the silicate particles is a common process in the ► [solar system](#). Prominent examples are the iron-rich cores of the terrestrial bodies and iron ► [meteorites](#) that consist of Fe-Ni alloys. The latter are assumed to be the fragments of the cores of larger ancient asteroids that have been shattered by impacts. Studies on short-lived radionuclides (e.g., ^{182}Hf) suggest

that the core formation process occurred during the first 5–30 million years of the solar system, prolonging with increasing size of the planetary body (e.g., Kleine et al. 2002). Thus, the differentiation event occurred most likely contemporaneously or shortly after completion of ► [asteroid](#) or planet accretion. The relatively rapid separation of silicate and iron implies that both components were fluid (Stevenson 1990). In case of small planetary bodies like the asteroids, the decay of short-lived radioactive isotopes like ^{26}Al and ^{60}Fe provides a sufficient amount of energy to melt the interior (e.g., MacPherson et al. 1995; Tachibana and Huss 2003). The presence of siderophile elements, i.e., elements such as S, Ni, and Co that are readily soluble in molten iron, would result in a significant melting-point depression (e.g., Braginsky 1964), thereby facilitating the segregation of iron alloys in the core. Once a metal core has formed, it may further differentiate as soon as an inner pure Fe core starts to solidify upon cooling. In turn, the fluid outer core then would be enriched in the low-melting-point components.

The formation of the secondary crust would deplete the mantle in radioactive elements and crust-forming minerals, as those are incompatible and enriched in the melt. In addition, the melt that forms the crust is enriched in volatiles that are released into the atmosphere by extrusive volcanism. Mantle degassing associated with crustal differentiation can play an important role for the evolution of planetary atmospheres. The mechanisms of crust formation differ between ► [plate tectonics](#) and one-plate planets. Plate tectonics provides for crust formation in a two-step fashion. Crust formation is most effective at divergent plate boundaries, where rising hot mantle material crosses the solidus near the surface. The corresponding pressure-release melting generates basaltic crust that is continuously recycled at convergent plate boundaries. More silicic crust is produced in a second differentiation step at convergent plate boundaries where basaltic crust is remelted (together with wet continental sediments and possibly mantle rock) to form new continental-like crust (e.g., Taylor and McLennan 1985). One important open question for the Earth with its plate tectonics is the timing of the

continental crust growth. Models range from rapid early crustal growth with crust production and recycling in equilibrium in the later evolution (Armstrong 1981), a continuous growth of the crust to its present size (Veizer and Jansen 1979), and an episodic growth with a peak at the Archaean-Proterozoic transition (Taylor and McLennan 1985). For one-plate planets in the ► [stagnant lid](#) convection regime, crust recycling is only possible in the form of crustal delamination for which the lower-dense crustal material (basalt that changes to eclogite at depth) sinks into the mantle and there is no two-stage differentiation. Instead, melt is formed underneath the lithosphere usually at greater depth as compared to planets with plate tectonics. The crust produced would predominately be composed of basaltic rock. Observations and thermochemical models show that for the Moon and ► [Mars](#), most of the basaltic crust is produced early in the planetary evolution (e.g., Nimmo and Tanaka 2005). ► [Venus](#) is distinct in that the surface has an average age of 300–800 Ma (Schaber et al. 1992). The uniform age distribution has been associated with a global resurfacing event, possibly associated with a change in the style of mantle convection (see Bougher et al. (1997) for a review). The relatively rapid global resurfacing of Venus may be questioned, since the cratering record allows a variety of interpretations in terms of volcanic resurfacing, including a global decrease in activity over time (Campbell et al. 1999).

Applications

The state of knowledge of planetary differentiation processes has important implications for the general understanding of the internal structure, thermochemical evolution, bulk composition, and atmosphere evolution of the terrestrial planets and terrestrial-type bodies like the Moon and several large outer-planet satellites. Even the interior of main-belt asteroid 4 Vesta (► [Vesta](#)) is likely differentiated (Ghosh and McSween 1998), as

suggested by the spectrally variegated surface of that accretional remnant.

Future Directions

To further our understanding of the internal differentiation and the associated volatile loss, new and improved techniques and methods will be developed and applied in the future. Among those are isotopic and trace element studies on planetary material, improved numerical techniques incorporating mantle melting and degassing in the frame of three-dimensional convection models, and also future missions applying new and improved measuring techniques.

Diffraction

Daniel Rouan

LESIA, Observatoire Paris-Site de Meudon,
Meudon, France

Definition

Diffraction, in physics, is a phenomenon that occurs when a wave encounters an obstacle or travels through a medium with a varying refractive index. Secondary radial waves issued from the obstacle spread out, the more widely as the size of the obstacle becomes smaller and approaches the wavelength. Because the secondary waves may interfere, the diffraction pattern generally shows structures with fringes or rings (see Fig. 1). Diffraction of light in observational astronomy limits the ability of an imaging system to resolve the finest details. The larger the aperture of the telescope and the smaller the wavelength, the finer the angular resolution. A quantitative expression of this limit is given by the expression $\theta(\text{arcsec}) = 0.2 \lambda(\mu\text{m})/D(\text{m})$, where λ is the wavelength in μm and D the diameter of the telescope in meters. This effect provides one justification for telescopes having very large mirrors, the other justification being better collecting

Diffraction,

Fig. 1 Diffraction pattern generated by a small hole in a dark screen illuminated by a beam of light and seen at a certain distance. Note the rings that are characteristic of this figure called the Airy pattern

power. However, on the ground (as opposed to space), telescopes are hampered by atmospheric turbulence that blurs the image to a typical resolution of 1 arcsec, whatever the size of the telescope is. Only ► [adaptive optics](#) techniques allow to recover the diffraction limit of a telescope.

Diffuse Cloud

William M. Irvine

University of Massachusetts, Amherst, MA, USA

Definition

A diffuse cloud is that portion of an interstellar cloud with visual extinction (A_v) less than about

1 magnitude, corresponding typically to densities of a few tens of atoms per cubic centimeter or less, and column densities of order 10^{21} hydrogen atoms cm^{-2} . Hydrogen, the principal constituent of interstellar clouds, is predominantly in atomic form in diffuse clouds. The physics and chemistry of diffuse clouds may be studied by observing the absorption lines produced in the spectra of background stars. Trace constituents observed at visual and ultraviolet wavelengths include many atoms and diatomic molecules, including such simple molecules as CO, OH, CH, CH^+ , CN, and H_2 . At millimeter wavelengths, molecules such as C_2H and HCO^+ are observed. As the density increases, diffuse clouds grade gradually into those clouds referred to as translucent and then to those that are called dense. The Herschel satellite has recently discovered OH^+ , H_2O^+ , H_2Cl^+ , and HF as constituents of diffuse interstellar clouds (Neufeld et al. 2010; Gerin et al. 2010; Lis et al. 2010).

Diffuse Interstellar Bands

Martin A. Cordiner

NASA Goddard Space Flight Center,
Astrochemistry Laboratory, Greenbelt, MD, USA

Keywords

Astrochemistry · Interstellar medium · Interstellar dust · Optical spectroscopy · Large molecules

Synonyms

[DIBs](#); [Diffuse bands](#)

Definition

The Diffuse Interstellar Bands (DIBs) are broad spectroscopic absorption features, of predominantly unknown origin, which occur in the optical and near-infrared spectra of stars as their light passes through the interstellar medium. More than 400 DIBs have been detected to-date at different wavelengths, at least some of which are believed to be caused by large carbon-based molecules such as fullerenes, polycyclic aromatics, and carbon chain-bearing species.

History

In 1922, Mary Lea Heger discovered two prominent dark absorption bands in the spectra of hot (early spectral type) stars at wavelengths of 5780 and 5797 Å (Heger 1922). The cause of these features could not be established at the time, and their origin remains unknown to this date.

Due to the detailed studies of binary stars by Merrill and Sanford (1938), the unidentified bands were determined to originate in the interstellar medium (ISM), and four additional bands were discovered in the red region of the spectrum, at wavelengths of 6203, 6270, 6284, and 6614 Å. The bands were noted as being somewhat diffuse, as they have a broader width than other interstellar absorption lines that are known to be caused by common gas-phase atoms (such as sodium and calcium) or simple molecules (such as CH and CN). Henceforth, these and other unidentified, broad interstellar absorption features in optical spectra came to be known as diffuse interstellar bands (DIBs).

More than 400 different DIBs are now known (Hobbs et al. 2009) and more are found with each increase in survey sensitivity, but apart from the recent attribution of two near-infrared bands to ionized buckminsterfullerene (C_{60}^+ ; Ehrenfreund

and Foing 1997; Campbell et al. 2015; Cordiner et al. 2019), the vast majority of the DIB carriers are yet to be definitively assigned.

Overview

The diffuse interstellar band problem is among the longest-standing mysteries in astrophysics and has confounded the efforts of astronomers and chemists since the early twentieth century. At least some of the DIBs are probably attributable to large, carbon-based molecules. The resolution of this mystery is therefore likely to be of relevance to theories regarding the chemical composition of the interstellar medium, and the evolution of complex organic molecules in space, and may therefore be of relevance astrobiological studies. Due to their ubiquity in the dusty interstellar medium and their chemical stability in harsh environments, the DIB carriers constitute a possible source of cosmic carbon delivered to the early Earth and other planetary surfaces.

Basic Methodology

Diffuse interstellar bands are most readily detected and analyzed in high-resolution, high signal-to-noise optical spectra of hot stars (with spectral types O and B). The interstellar bands may be distinguished from stellar lines through multi-epoch observations of spectroscopic binary stars or by comparison with un-reddened standard stars. Variations in DIB spectra may be studied with respect to interstellar physical and chemical conditions in order to elucidate the nature of the carriers. The spectra are carefully compared with laboratory and theoretical data to test hypotheses regarding potential carriers. To assign a DIB carrier is very difficult because it requires a precise spectroscopic match between the DIB and the proposed carrier spectrum, at temperature, density, and radiation conditions matching those of the diffuse interstellar medium (ISM) where the carriers reside.

Key Research Findings

Observational Constraints on the DIB carriers

Throughout our Galaxy, the strengths of many of the diffuse interstellar bands are closely correlated with the amount of interstellar dust, which causes reddening of starlight. This suggests a possible origin in small solid particles that are known in the laboratory to exhibit broad optical absorption lines. Diffuse interstellar bands are observed in low-density regions of the interstellar medium whenever dust is present, and even in regions pervaded by intense, hard ultraviolet radiation that rapidly destroys all but the hardest molecular material. However, the correlation between DIB strengths and amount of dust is imperfect, with a scatter of about a factor of two about the mean for a given reddening (for the well-studied 5780 Å DIB; see Herbig 1993), which constitutes evidence against a solid-state carrier particle. In addition, the relative constancy of the DIB wavelengths across different astrophysical environments, the lack of any light polarization signature inside the DIB profiles and the lack of emission adjacent to the DIBs makes interstellar dust an unlikely carrier. Discussions on the viability of various carrier candidates are given by Herbig (1995), Snow (1995), and Sarre (2006).

Strong evidence that several DIBs are caused by gas-phase molecules is given by the observation of diffuse bands in emission in the Red Rectangle nebula (Sarre 1991; Fossey 1991). The wavelengths of these emission bands are close to those of a subset of relatively narrow diffuse interstellar bands, and the steep blue side and red-degraded tails are typical of electronic transitions in large, cold molecules.

Further evidence for large, carbonaceous carrier molecules is given by close examination of the shapes of many of the strongest diffuse interstellar bands, which reveal complex profiles with fine structure similar to that seen for various classes of large (gas-phase) molecules in the laboratory, including long carbon-chains, polycyclic aromatic hydrocarbons (PAHs) and fullerenes. The fine structure of these DIB profiles is observed to be variable, perhaps as a result of changes in the internal temperature, excitation,

Diffuse Interstellar Bands, Fig. 1 The 5780 and 5797 Å DIBs observed towards the Milky Way (MW) star β^1 Sco (top), the Andromeda (M31) star MAG 63885 (middle), and the Large Magellanic Cloud (LMC) star Sk -69,223 (bottom). Extragalactic DIBs are shifted from their

Galactic wavelengths due to the systemic Doppler motions of their host galaxies. (Data are from Cordiner et al. (2008); Cox et al. (2006). Spectra have been normalized and offset vertically for display. The MAG 63885 data have a fitted profile overlaid in red)

or isotopic composition of the carriers. DIB widths are consistent with carrier molecules containing at least about 20 atoms.

DIB strengths correlate well with the amount of neutral gas (such as H I and Na I), but not with the denser molecular gas traced by H_2 , as demonstrated by Herbig (1993). The DIB carriers are not, therefore, closely associated with the chemistry of those molecules that are typically most abundant in dense molecular environments where stars form and UV radiation fields are low. Indeed, various studies have shown that DIBs tend to be relatively weak inside dense molecular clouds (e.g., Adamson et al. 1991).

The fact that DIBs are observed most strongly in the relatively unshielded diffuse clouds with low extinction indicates that the carriers are resistant to destruction by UV radiation, so they cannot be small molecules, which tend to be easily photo-dissociated.

Observations of diffuse band properties in extreme environments may help elucidate the nature of the carrier. To that end, research into

the properties of diffuse interstellar bands outside the Milky Way is currently in progress (see for example, Cox et al. 2006; Cordiner et al. 2011), and although the DIB strengths show some deviation from the trends observed in the Milky Way (presumably as a result of the differing physical and chemical conditions in these environments, including the metallicity and interstellar radiation field strength), their overall spectrum is similar to that observed in our Galaxy. Two of the best-studied DIBs are found at rest wavelengths of 5780 and 5797 Å. Spectra of these DIBs are shown in Fig. 1, observed towards stars in the Milky Way, the Andromeda Galaxy, and the Large Magellanic Cloud.

DIB Carrier Candidates

Carbon is unique in its ability to form large, complex molecules. It is also one of the most abundant chemical species in the interstellar medium, where it exists in the form of neutral and ionized atoms, polyatomic molecules, aromatics, and dust grains. The fact that there are so many

different DIBs, each apparently caused by a different, large gas-phase molecule, is strongly suggestive that the molecular structures of at least some, and perhaps the majority of the carriers are composed predominantly of carbon.

Large, carbon-based molecules, such as polycyclic aromatic hydrocarbons (and the various classes of PAHs that have been modified, for example, by ionization, protonation, or dehydrogenation), are stable and resistant to destruction by UV radiation. Such aromatic molecules are believed to be abundant in the diffuse ISM where DIBs are strongest, and therefore represent an attractive class of possible carriers. This hypothesis has been reviewed by several authors (Crawford et al. 1985; Leger and D'Hendecourt 1985; Salama et al. 1999). Laboratory spectroscopy has shown that PAHs and their ions possess strong electronic transitions in the optical (e.g., Ruiterkamp et al. 2002; Tan and Salama 2006; Useli-Bacchitta et al. 2010). However, after extensive laboratory and theoretical studies of the spectroscopy of a plenitude of PAHs and related aromatics, no DIB has yet been assigned to any specific PAH-type molecule.

Following the suggestion of Kroto in the 1980s that C_{60} and other fullerenes might be present in the ISM (see Kroto and Jura 1992), Ehrenfreund and Foing (1997) examined the possibility of C_{60}^+ as the carrier of two DIBs in the near infrared. Thanks to recent advances in low-temperature laboratory spectroscopy, Campbell et al. (2015) confirmed a precise match between the laboratory and interstellar wavelengths of the two strongest (9577 and 9632 Å) C_{60}^+ bands. Detections of additional, weaker C_{60}^+ interstellar bands (at 9635 and 9428 Å) have also been claimed (Walker et al. 2015), so that the C_{60}^+ assignment now enjoys widespread acceptance. It should be emphasized, however, that obtaining a clean interstellar spectrum in this wavelength range is made difficult as a result of severe telluric contamination, as well as the presence of overlapping stellar features. The presence of the weaker C_{60}^+ bands was confirmed by Cordiner et al. (2019) using Hubble Space Telescope spectra of nine heavily-reddened Galactic sightlines. This places the assignment of interstellar C_{60}^+

beyond reasonable doubt, and confirms the chemical importance of fullerenes in diffuse environments. Other large, ionized, carbon-based molecules must now be considered as strong candidates to explain some of the remaining, unidentified DIBs.

Other related large molecules that have transitions in the optical include carbon nanotubes, “Bucky onions” and graphene sheets. Such stable, carbon-based molecules, which span the continuum of sizes from large molecules to small dust grains, may be injected into interstellar space in the outflows from dying stars, later to be incorporated into the next generation of star and planet-forming regions.

Theoretically, the addition or substitution of other atoms inside or at the periphery of aromatic carbon structures, either during the formation of the molecules or during their subsequent journey through the interstellar medium, results in molecules of biological relevance that may constitute potential DIB carriers. For example, the alkylation and oxidation of aromatic molecules in interstellar ice analogues (Elsila et al. 2006) results in the addition of methyl and hydroxyl side groups of the kind found in biomolecules. Heterocyclic aromatic organic compounds, including biologically important nitrogen heterocycles, are probably also present in the ISM and are theorized to be produced from reactions involving C_2H_2 and HCN in stellar outflows (Hudgins et al. 2005). Although they are less stable to UV degradation than PAHs, larger nitrogen heterocycles (containing at least 50 carbon atoms) should be able to survive in the diffuse ISM to act as possible DIB carriers.

Heteroatoms can also be added to large carbonaceous molecules in unusual ways to modify their optical properties. For example, iron atoms bond to the delocalized electron clouds above aromatic rings to form so-called organometallics. During the formation of fullerenes, metal atoms have a propensity to become trapped inside the carbon cage. Such species highlight the diversity of molecules that must be considered in the search for plausible DIB carrier candidates.

Some DIBs may be due to smaller organic molecules; close spectroscopic matches of the

8,037 Å DIB with CH_2CN^- and the 4,881 and 5,450 Å DIBs with $I\text{-C}_3\text{H}_2$ have been identified by Cordiner and Sarre (2007) and Maier et al. (2011), respectively. Radio astronomical absorption line studies of diffuse sightlines toward background quasars (Liszt et al. 2012, 2018) determined the presence of insufficient $I\text{-C}_3\text{H}_2$ for it to be a viable DIB carrier. However, the CH_2CN column density upper limit remains consistent with CH_2CN^- as a DIB carrier provided the anion-to-neutral ratio is in the range 17–50%.

Applications

Diffuse interstellar bands are clearly visible in reddened spectra of luminous objects throughout the universe. Once identified, the ubiquity of the DIBs will make them invaluable as probes of galactic interstellar chemistry and physics. Presently, their strengths are useful measures of the amount of interstellar dust in a sightline, and as tracers of a broad class of large organic molecules in space. The assignment of C_{60}^+ as carrier of two strong DIBs (and two weak DIBs) in the near infrared highlights the likely presence of a population of very large carbon-based molecules that have so far eluded detection, and thus sheds light on a previously unappreciated chemical complexity in the diffuse interstellar medium.

Future Directions

Further studies are required on how variations in interstellar physical and chemical conditions affect the DIB spectrum in order to further elucidate the properties of the carriers. In particular, the examination of peculiar or extreme interstellar environments in our Galaxy and beyond is likely to yield information in this regard. Continuing dedicated laboratory and theoretical efforts are necessary to determine the optical spectra of candidate carriers in order to make or rule out DIB assignments. Additional, detailed laboratory and theoretical studies of fullerenes and other

large molecules related to C_{60}^+ , are strongly justified to help unlock the remainder of the (still largely unsolved) DIB problem.

Diffusion

Sylvia Ekström

Observatoire Astronomique de l'Université de Genève, Faculté des Sciences, Université de Genève, Versoix, Switzerland

Definition

Diffusion refers to an irreversible transport process acting at the molecular scale and by which the density of a quantity X (e.g., the mass fraction of a chemical element) changes with time. The driving mechanism for the mixing is generally the density gradient ∇X , and the result is to homogenize the density throughout the considered region. The general form of the equation of diffusion can be written as

$$\frac{\partial}{\partial t}(\rho X) = \nabla \cdot (\rho D \nabla X)$$

with ρ the mass density of the medium (with units [mass length⁻³]) and D the diffusion coefficient (with units [length² time⁻¹]) or *diffusivity*. The characteristic timescale for diffusion is:

$$\tau_{\text{diff}} \propto \frac{\ell^2}{D}$$

with ℓ the characteristic size of the considered region.

Definition

A diketopiperazine is a cyclic dimer of two peptide-bonded ► [amino acid](#) molecules.

Overview

Amino acids, delivered via extraterrestrial delivery or synthesized by Miller-Urey-type chemistry, may have been available in abundance on the primitive Earth and may be abundant via these sources on other planets as well. Subsequent chemical evolution would require the synthesis of oligopeptides from the amino acid monomers. If a source of energy driving the formation of peptides is available in the form of geothermal heat exposed to the ocean as in hydrothermal

environments on Earth, diketopiperazines could quite easily be synthesized with the aid of the heat energy. The ease with which diketopiperazine is formed is a result of the presence of both a free amino group and a free carboxylic group residing in a single dipeptide once the latter is synthesized. A dipeptide having only one peptide bond linking its two units initially is unstable against transformation into a diketopiperazine with two peptide bonds in a closed-ring form.

At first sight, diketopiperazine may look like a dead end for chemical evolution since there is no room for making additional peptide bonds. However, this is a hasty conclusion. There is certainly a possibility for opening up the once-closed ring of peptide bonds when the surrounding conditions are changed. If the amount of diketopiperazine synthesized in the reaction solution becomes sufficiently high, the reaction of an amino acid molecule aminolyzing a diketopiperazine to form a tripeptide is actually confirmed experimentally (Nagayama et al. [1990](#)). The ring opening is due to the nucleophilic attack of an amino acid molecule's amino group on the diketopiperazine. The similar nucleophilic attack on diketopiperazine by an amino group of an oligopeptide is also possible, which results in an oligopeptide two amino acids longer.

Elongation of an oligopeptide through the aminolysis of diketopiperazine could play a significant role in the prebiotic evolution of oligopeptides, especially in the respect that the elongation could take place even in the absence of guiding templates. In other words, if there happens to appear a reaction environment in which both monomeric amino acids and diketopiperazines are supplied in abundance, a wide variety of oligopeptides could be synthesized. Some functional oligopeptides could be formed, even at the stage prior to the emergence of nucleotide or oligonucleotide molecules serving as reaction templates.

Dinitrogen

Henderson James Cleaves

Earth-Life Science Institute (ELSI), Tokyo

Institute of Technology, Tokyo, Japan

Blue Marble Space Institute of Science,

Washington, DC, USA

Center for Chemical Evolution, Georgia Institute of Technology, Atlanta, GA, USA

Keywords

Extreme UV · Photochemistry · Neutral atmosphere · Nitrogen (atomic) · Ammonia · Nitrogen cycle · Nitrogen fixation

Synonyms

[Molecular nitrogen](#); [N₂](#); [Nitrogen gas](#)

Definition

Dinitrogen is a chemical compound formed from the covalent bonding of two nitrogen atoms. It is a colorless, odorless gas at room temperature and pressure, which makes up approximately 78% of the Earth's atmosphere (by volume). It is also the major component of the atmosphere of ► [Titan](#) (one of Saturn's moons). Dinitrogen exhibits remarkable stability and is remarkably chemically inert. Liquid dinitrogen is widely used as a cryo-coolant (b.p. 196 °C at atmospheric pressure).

Overview

Dinitrogen (N₂) refers to ► [nitrogen](#) occurring in the diatomic form (its most stable form), also commonly called molecular nitrogen or nitrogen gas, in which two nitrogen atoms are linked by a triple covalent bond (which fills the Lewis electron rules; the two lone, nonbonding electron pairs, one on each N atom, lie at a quite low energy level). N₂ is commonly used as a laboratory or industrial cryo-coolant, as it has a boiling point of –196 °C and a melting point of –210 °C at atmospheric pressure.

Monoisotopic molecular nitrogen (N₂) is largely transparent to infrared and visible radiation because it is a homonuclear molecule and has no electric dipole moment to couple to electromagnetic radiation at these wavelengths. Significant absorption occurs in the extreme ultraviolet region, beginning around 100 nm. This absorption of UV light by N₂ is important in the Earth's upper atmosphere and the atmospheres of other planetary bodies.

Measurements of the energy required to form ► [ammonia](#) from N₂ and H₂ reveal that N₂ is unusually stabilized relative to its carbon analogue, ► [acetylene](#), because of the strength of the nitrogen-nitrogen triple covalent bond in N₂. This feature dominates the chemistry of dinitrogen, which is very unreactive at standard

temperature and pressure, thus making it (despite its abundance on Earth) a difficult-to-fix source of elemental nitrogen for living organisms.

The conversion of dinitrogen into biologically useful compounds (usually having N at an oxidation state other than zero) is called ► “[nitrogen fixation](#),” which is extremely important in both biological and abiological nitrogen cycling. Biological nitrogen fixation by bacteria in the root nodules of plants produces ammonia (Leigh and Dodsworth 2007). This N_2 to NH_3 reduction (which is by far the major natural nitrogen source for currently living organisms) is catalyzed by nitrogenase enzymes, the active sites of which contain Fe and Mo atoms, using energy derived from the hydrolysis of adenosine triphosphate and requiring anoxic conditions.

Abiotic nitrogen fixation occurs in nature through lightning in the atmosphere, which produces NO_x species (Hill et al. 1980), thanks to very high temperatures produced in the immediate vicinity of lightning bolts, followed by rapid thermal quenching that traps high-energy species, or through photocatalysis over various metal-oxide-containing minerals (Schrauzer et al. 1983). For comparison, uncatalyzed N_2 photochemistry in the Earth’s upper atmosphere is much less efficient. Precipitation often contains substantial quantities of ammonium and nitrate, much of it produced by lightning and other atmospheric electrical phenomena.

Decay of organisms and their waste products results in the formation of nitrate, which eventually may return to the atmosphere as dinitrogen through the microbial reduction of nitrate in a process known as “denitrification.”

Dinitrogen is thought to be a major reservoir of N in interstellar ► [molecular clouds](#), although it cannot be directly detected in these cold regions. Instead, its abundance is deduced from observations of its protonated derivative, N_2H^+ , which has strong pure rotational transitions in the 3-mm region of the spectrum. Besides the Earth, Saturn’s moon Titan is the only other known planetary body with a dense atmosphere mostly made of dinitrogen, the origin of which is not yet fully understood.

Dioxygen

Hiroshi Ohmoto

NASA Astrobiology Institute and Department of Geosciences, The Pennsylvania State University, University Park, PA, USA

Keywords

Atmospheric oxygen · Evolution of the atmosphere · Oxygen geochemical cycle · Oxygenic photosynthesis

Synonyms

Molecular oxygen; O₂; Oxygen (molecule)

Definition

Dioxygen is a molecule formed by the covalent binding of two oxygen atoms. At standard temperature and pressure, it occurs as a stable gas. O₂ condenses at 90.20 K and freezes at 54.36 K.

Overview

The present atmospheric level (PAL) of molecular oxygen (O₂) is 0.209 atm, corresponding to 3.7×10^{19} moles of O₂ in the atmosphere (Holland 1978). The dissociation of water (H₂O) in the atmosphere and shallow ►water by UV light is one source of atmospheric O₂:

If hydrogen (H₂) can easily escape into space, such as on Mars where the gravity is much less than on Earth, O₂ can continue to accumulate in the atmosphere by Reaction (1) alone.

On Earth, a significant production of O₂ requires a continuous consumption of H₂ in the reduction of ►carbon dioxide (CO₂) by organisms:

When Reactions (1) and (2) occur simultaneously within cells of organisms in the photic zone, such as ►cyanobacteria, ►algae, and plants, it is better known as oxygenic ►photosynthesis:

Currently, terrestrial and marine organisms each produce about 3×10^{15} moles/year of O₂ (and also of organic C) (Holland 1978). Essentially, all of the organic carbon and O₂ produced by terrestrial organisms is converted back to CO₂ and H₂O by the reverse of Reaction (3). Thus, terrestrial organisms have not contributed to the long-term (>1000 year) accumulation of atmospheric O₂. The long-term input of O₂ to the atmosphere has been attributed mostly to the burial of organic matter (and some to the burial of pyrite) in marine sediments, which prevents the reverse Reaction (3) and causes the accumulation of O₂ in the atmosphere. About 0.3% of the total organic C produced in the oceans is buried in sediments to provide about 10^{13} moles/year of O₂ as the long-term atmospheric input (Holland 1978; Lasaga and Ohmoto 2002). The long-term output (consumption) of atmospheric O₂ has been carried out primarily by (a) the oxidation of reducing volcanic gases (e.g., H₂, ►carbon monoxide (CO), ►methane (CH₄), ►hydrogen sulfide (H₂S), and sulfur dioxide (SO₂)) and (b) the weathering of reduced compounds in rocks (e.g., organic C, ferrous ►iron, and reduced ►sulfur) (Lasaga and Ohmoto 2002; Kasting 1987). Today, the long-term fluxes of O₂ production and consumption appear to be balanced (Holland 1978; Lasaga and Ohmoto 2002).

The atmospheric *p*O₂ level before the emergence of cyanobacteria at time T₁ has been estimated to be $\sim 10^{-12}$ PAL, in which the reducing gases (H₂ and CH₄) were more abundant than O₂ (Kasting 1987). O₂ became more abundant than reduced gases at *p*O₂ > $\sim 10^{-5}$ PAL (Pavlov and Kasting 2002) at

Dioxygen, Table 1 Theories for the oxygenation of the atmosphere and oceans

Time	T ₁	T ₂	T ₃	T ₄
Atmospheric <i>p</i> O ₂ Level (PAL)	~10 ⁻¹²	~10 ⁻⁵	~5%	~50%
Oxygenic Photoautotrophs				➤
Oxic Atmosphere (<i>p</i> O ₂ > <i>p</i> H ₂)				➤
Oxic Photic Zone				➤
Oxic Deep Oceans				➤
Time before Present (Ga) (Theory 1)	~2.7	~2.4	~2.4	~0.6
Time before Present (Ga) (Theory 2)				>3.5

T₂, the photic zone became suitable environments for aerobic organisms and eukaryotes at *p*O₂ > ~5% PAL (Jahnke and Klein 1983) at T₃, and deep (as well as shallow) oceans became oxygenated at *p*O₂ > ~50% PAL (Kasting 1987; Sarmiento 1992) at T₄ (see Table 1).

The theory accepted by most astrobiologists postulates the ages of ~2.7 Ga (T₁), ~2.4 Ga (T₂ and T₃), and ~0.6 Ga (T₄), and a subsequent gradual rise of atmospheric *p*O₂ to the present level (Kasting 1987; Pavlov and Kasting 2002; Anbar and Knoll 2002). However, some mineralogical, geochemical, and paleontological observations (Ohmoto 2004; Hoashi et al. 2009) suggest that the placements of T₁–T₄ may have occurred before 3.5 Ga and that the atmospheric *p*O₂ level has been maintained within a range of 0.6–2 PAL since T₁ by a series of negative feedback mechanisms (Lasaga and Ohmoto 2002).

Dirac, Paul

Fernando B. Figueiredo
CITEUC, University of Coimbra, Coimbra,
Portugal

History

Paul Adrien Maurice Dirac (1902–1984) was a British quantum physicist awarded in 1933 with the Nobel Prize (which he shared with Schrödinger) for the “discovery of new productive forms of atomic theory.”

Dirac established, independently of Fermi, the statistical laws (now called Fermi-Dirac statistics) that ruled fermions, particles systems subject to the Pauli exclusion principle. His scientific work led to introduce the concept of antimatter, which plays a central role in modern particle physics and cosmology.

In 1932 Dirac was appointed Lucasian professor of mathematics at the University of Cambridge, which was also Newton’s chair. Stephen Hawking was Dirac’s successor in the Lucasian chair.

Direct-Imaging, Planets

Marc Kuchner
Exoplanets and Stellar Astrophysics Laboratory,
NASA Goddard Space Flight Center, Greenbelt,
MD, USA

Definition

Direct imaging of planets refers to the effort to detect and study exoplanets from the light emitted or scattered by the planets themselves, as opposed to inferring the existence and properties of planets from their effects on the images or spectra of the stars they orbit. Directly imaging an exoplanet, that is, collecting light from the planet and distinguishing it from light from the host star, which requires special instruments to overcome distortions caused by conventional telescope optics and the atmosphere. The challenge of developing these instruments – coronagraphs and interferometers with adaptive optics systems – has caused direct imaging to lag behind other exoplanet detection techniques. But direct imaging offers access to planets with host stars and orbital properties that make them unreachable by other techniques, and a means to find Earth-like planets around nearby stars and characterize their atmospheres. The few planets that have been detected by direct imaging so far tend to be hot, young giant planets, located far (>20 AU) from their host stars. The presence of such objects presents a challenge for some theories of planet formation.

History

In 2005, Chauvin et al. ([2005](#)) imaged a ~ 5 Jupiter-mass companion to a nearby brown dwarf using the VLT/NACO. Imaged planets have also been reported in the HR 8799 and Fomalhaut systems, though the masses of these objects remain uncertain and some of them may

turn out to be in the brown dwarf, rather than planet, mass range. The directly imaged planet with the closest orbit (8 AU) to its star has been reported in the Beta-Pic system by Lagrange et al. (2010).

Discovery of Extraterrestrial Life

Klara Anna Capova
Department of Anthropology, Durham University,
Durham, UK

Acronyms

- | | |
|------|--|
| METI | Messaging to Extraterrestrial Intelligence |
| SETI | Search for Extraterrestrial Intelligence |
| SETL | Search for Extraterrestrial Life |

Definition

The discovery of extraterrestrial life, a solid scientific evidence that either past or present life forms exist or have existed elsewhere in the

universe, is often referred to as one of the greatest discoveries of science. Such evidence for extraterrestrial life either within the Solar System or exoplanetary systems would answer the longstanding questions about whether or not we are alone in the universe, and about where we have come from. Given its philosophical, societal, and cultural importance, the anticipated global reach of and reaction to the discovery are profound and world-view changing.

Overview

Likely inspired by the historical accounts of the first contact between societies on Earth, the opinions about how the discovery of extraterrestrial life will unfold, tend to favor scenarios that involve a profound cultural shock, followed by an inevitable and irreversible societal change, and in some cases, even armed conflict. The explanation for such views is in the assumption that an intelligent, sentient, advanced life-form – a civilization similar to ours – will be discovered. Here, it plays an important part in the works of science fiction, most notably H. G. Well's novel "War of the Worlds" from 1897 (first published in 1898). Wells described the invasion of an alien, technologically superior race from Mars as a catastrophic event with global impact followed by a collapse of social order. This captivating story became a classic piece of literature and a landmark work of the science fiction genre. In 1939, when Orson Welles adapted the novel for a radio broadcast, the on-air dramatization of an alien attack caused a nationwide panic amongst at least one million of its listeners in the US (Cantril et al. 1966). To date, these fictional stories are reflected in the popular imaginations of what the discovery of extraterrestrial life could be like.

History of science shows us that the scientific search for life beyond Earth as a systematic activity dates to the second half of the twentieth century. Marking the era of "searches," the scientific community around American astronomers Carl Sagan and Frank Drake has undertaken the first

steps in active search for life beyond earth known as METI – Messaging to Extraterrestrial Intelligence. In 1972, NASA launched Pioneer 10 spacecraft carrying a small plate, now known as Pioneer Plaque, with engraved symbols intended for an intelligent receiver. In 1974, a radio transmission was sent from Arecibo radio telescope with the “1979 bits of information” carrying basic information about Earth and its inhabitants. The Voyager Golden Record (1977), a phonograph record containing a selection of photos, music, sounds, and greetings from Earth, was attached to Voyager 1 and Voyager 2 space probes that have since become the cultural icons of the Space Age. It should be noted that, historically, the first message sent to outer space was the “Message to Venus” in 1962 – composed of three Russian words in the Morse code sent from the former USSR. Gradually, METI has become an international activity.

Another method of the search for intelligent life-forms is SETI: Search for Extraterrestrial Intelligence that was formed in the 1980s (for more see SETI, History of, and SETI). Also called “passive search,” SETI activities involve coordinated effort to find technological civilizations that may exist elsewhere in the universe. By the use of radio technology, SETI’s activities focus on detecting the scientific evidence of past or present technology: techno-signatures. Both METI and SETI presume an intelligent, curious, advanced, scientifically literate, and possibly humanoid extraterrestrial life-forms, with technologies capable of intercepting (METI) or transmitting (SETI) a message.

Astrobiology, in contrast, operates with a distinctly different concept of extraterrestrial life and we have observed a paradigm change in the scientific search for life beyond Earth. The shift from searching for complex, sentient, intelligent life (METI, SETI) to searching for origins of life or life in its basics, as described by American anthropologist Helmreich: “No longer culture, but nature. No extraterrestrial messages but other-worldly organisms.” (Helmreich 2009). Such life – or even suitable conditions for it to emerge and evolve – could be found on Mars, other planets of the Solar System, or on exoplanets.

The new paradigm ushers in a different type of societal response to the discovery. Work entitled “Search for Past Life on Mars: Possible Relic Biogenic Activity in Martian Meteorite ALH 84001” published in 1996 by David S. McKay is a recent example of how the discovery unfolds in a real-life situation. The chain structures revealed in the ALH 84001 meteorite originating from Mars led the scientific team to a conclusion that the structures might be the evidence for a primitive life on early Mars (McKay et al. 1996). Despite the nonconclusive evidence, the publication was followed by a keen interest by major news networks, public discussions, and recognition of its societal importance. This included the US President Clinton’s Statement regarding Mars meteorite discovery and potential far-reaching implications of the possibility of life elsewhere.

Given the immense cross-cultural differences within humankind, it is reasonable to assume that the societal response to the discovery of extraterrestrial life will not be globally uniform or universal. Rather, a variety of cultural, social, historical, religious, and even political factors would shape the short-term effects and long-term impacts. The deciding factors as to what the societal reaction will be like are in the very characteristics and attributes of the life-forms newly discovered.

Keywords

Planet formation · Protoplanetary disk · Q (Toomre parameter)

Synonyms

[Gravitational instability \(Model for Giant Planet Formation\)](#)

Definition

The disk instability model suggests that ► [gas giant planets](#) form directly as a result of (local) gravitational instabilities in the ► [protoplanetary disk](#). Numerical simulations have shown that clumps of various masses can form in sufficiently gravitationally unstable disks. Protoplanetary disks can become gravitationally unstable if they are sufficiently cool and/or massive. The condition for gravitational instability can be determined from the value of the Toomre parameter Q . Protoplanetary disks will be unstable for $Q < \sim 1$. Once a local instability occurs, a gravitationally bound sub-condensation region (clump)

Disinfection

J. Andy Spry
SETI Institute, Mountain View, CA, USA

Definition

Disinfection is a process performed to reduce (by removal or inactivation) the number of viable microorganisms present in an environment (gas, liquid, surface, etc.). Typically, a disinfection approach is process-driven, rather than bioburden outcome-driven, and may use less precise process control parameters and bioburden reduction verification than Pasteurization or sterilization procedures. In planetary protection, disinfection may be a precursor process to a more controlled sterilization process.

is created. If the cooling time in this region of the disk is shorter than (or comparable to) the dynamical time, the fragment contracts, and eventually evolves to become a giant planet. The masses and survivability of clumps formed in the disk instability model are still being investigated. In addition, it is yet to be determined whether the forming objects significantly change their masses, compositions, and orbital locations after they form.

[SS-bond](#)

Definition

A disulfide bond is a covalent bond between two sulfur atoms (-S-S-) formed by the coupling of two ► [thiol](#) (-SH) groups. ► [Cysteine](#), one of the 20 protein amino acids, has a thiol group in its side chain and can easily be dimerized to ► [cysteine](#) in aqueous solution by forming a disulfide bond. In many protein molecules, disulfide bonds between cysteine residues are essential for protein folding. Disulfide bonds in proteins are cleaved by heating or by the addition of reducing reagents, which leads to protein denaturation.

Dixon Island Formation, Western Australia

Nicholas Arndt
Maison des Géosciences, LGCA, Université
J. Fourier, St-Martin d'Hères, France

Definition

The Dixon Island Formation is a 3.2-Ga-old sequence of lightly metamorphosed but highly silicified cherts, organic-rich black shales and tuffs belonging to the Cleaverville Group and located in the ► [Pilbara Craton](#), Western Australia. The unit is thought to have formed through shallow marine hydrothermal alteration of Archean ► [oceanic crust](#). Possible microbial mats and bacteria-like structures have been observed and are considered by some to be traces of early life. The sequence was the target of the Dixon Island-Cleaverville Drilling Project (DXCL-DP). The most important objective of the DXCL-DP was to understand the nature of the Middle Archean marine environment, influenced by hydrothermal activity, through detailed and systematic study of fresh drill core samples.

Synonyms

[German Aerospace Center](#)

Definition

The organization later called the DLR originated in 1969 as the Deutsche Forschungs- und Versuchsanstalt für Luft- und Raumfahrt (DFVLR; “German Test and Research Institute for Aviation and Space Flight”); it was formed from the merger of several previously existing institutions. In 1989, the DFVLR was renamed with the initials DLR and in 1997 was merged with the Deutsche Agentur für Raumfahrtangelegenheiten (DARA) to create the present DLR, the Deutsches Zentrum für Luft- und Raumfahrt, referred to as the German Aerospace Center in English language publications.

History

DLR’s mission comprises research aimed at protecting the environment; development of environmentally friendly technologies; and exploration of the Earth, the Solar System, and space, which leads to new knowledge about the origin and development of the Solar System, its planets, and, hence, about the emergence of life. The space activities include Germany’s national space program, and Germany’s contributions to the ► [European Space Agency \(ESA\)](#) as well as the European Organization for the Exploitation of Meteorological Satellites (EUMETSAT). Germany is a major contributor to the ESA mandatory program and also to the optional programs.

Over the years, Germany has been able to implement more than 100 space missions both nationally and within the framework of international cooperation. The DLR’s programs have involved planetary research, manned space flight, and related Earth-based research and development. The DLR has facilities at 14 locations in Germany: Augsburg, Berlin, Bonn, Braunschweig, Bremen, Cologne (headquarters), Goettingen, Hamburg, Lampoldshausen, Neustrelitz, Oberpfaffenhofen, Stuttgart, Trauen, and Weilheim.

Definition

DNA (deoxyribonucleic acid) is the polymer that stores the genetic information of all living cells and many viruses. DNA is a linear polymer of phosphodiester-linked 2′-deoxyribose sugars with heterocyclic bases (nucleobases) attached to the 1′ carbon of the 2′-deoxyribose sugars. The four nucleobases of DNA are adenine (A), guanine (G), cytosine (C), and ► [thymine \(T\)](#). DNA within a living cell primarily exists in the form of a double helix in which two polymer strands are held together by Watson-Crick base pairs (i.e., A-T and G-C base pairs).

Overview and Key Research Findings

DNA was discovered by Johann Friedrich Miescher in 1863. He separated the so-called nuclein from cells and showed that it was a previously uncharacterized phosphorus-containing material and hypothesized its involvement in heredity (Dahm 2005). It was not until 1944 that this hypothesis was confirmed, when Oswald Avery, Colin MacLeod, and Maclyn McCarty demonstrated that DNA taken from a disease-causing strain of the bacterium *Streptococcus*

pneumoniae permanently transformed a non-virulent form of the organism into a virulent one (Avery et al. 1944). Additional evidence was provided in 1951 by Alfred Hershey and Martha Chase, who demonstrated that when the bacteriophage T2 infects *Escherichia coli*, it is the DNA of the bacteriophage, not its protein coat, which enters the host cell and provides the genetic information for bacteriophage replication (Hershey and Chase 1951).

The double-helix structure of DNA was first proposed by James D. Watson and Francis Crick in 1953 (Watson and Crick 1953). The Watson-Crick model was largely based on X-ray fiber diffraction data of DNA obtained by Rosalind Franklin and Raymond Gosling (Franklin and Gosling 1953) and subsequent diffraction patterns obtained by Maurice Wilkins and coworkers (Wilkins et al. 1953). Biochemical information obtained by Erwin Chargaff regarding the 1:1 stoichiometry of G:C and A:T in DNA extracted from a wide range of organisms also facilitated Watson and Crick's elucidation of the double-helix structure (Elson and Chargaff 1954). Crick, Watson, and Wilkins shared the 1962 Nobel Prize in Physiology and Medicine for their contributions to determining the structure of the DNA double helix.

DNA Structure

The *primary structure* of DNA is generally described in terms of nucleotides, the molecular unit defined as a nucleobase connected by a glycosidic bond at the 1' position of a phosphorylated 2'-deoxyribose sugar. Along the backbone of a DNA polymer, or strand, nucleosides are connected to each other through the phosphate groups. A phosphodiester linkage exists between the 3' position of each ► nucleoside and the 5' position of the next nucleoside along a given DNA strand (Fig. 1). The order of deoxyribose nucleotides (dA, dG, dC, and dT) along a strand is the chemical basis for coding the genetic information contained within a DNA polymer. A single ► nucleotide that is not phosphorylated, that is, only the base connected to the sugar, is referred to as a nucleoside.

The repeating 3'-phosphate-5' linkages between nucleotides provide the polymer directionality for DNA that is inseparable from its synthesis and function. For example, DNA is synthesized by natural polymerases in the 5'-3' direction. That is, a DNA polymer being extended by a polymerase will have new nucleotides added to the terminal nucleotide at the free 3'-OH group.

The *secondary structure* of DNA within living organisms is predominantly a double helix formed by two strands with *complementary* nucleotide

DNA, Fig. 1 The chemical structure of DNA which illustrates Watson-Crick base pairing and the directionality of the deoxyribose-phosphodiester backbone

sequences, that is, sequences that support Watson-Crick base pairing along their entire lengths. The two strands of a Watson-Crick double helix run in opposite directions (as defined by the directionality of their polymer backbones) (Fig. 1). A Watson-Crick duplex is therefore said to have an antiparallel arrangement of its two strands. While complementary hydrogen bonding between nucleobases (i.e., A with T; G with C) provides specificity for base-pair formation, interstrand nucleobase stacking interactions apparently provide the most significant energetic contribution to helix stability (Yakovchuk et al. 2006).

The predominant helical structure of DNA within a cell and in vitro at high humidity (e.g., above 95% relative humidity) is known as the B-form helix (Fig. 2). The B-form helix is approximately 2 nm wide with a right-handed twist and a helical rise of around 3.4 nm per ten nucleotides. One complete turn of the B-form helix therefore consists of 10–10.5 base pairs. The B-form helix has two grooves that are of different widths and depths (Fig. 2). The wider groove is referred to as

the *major groove* and the narrower one as the *minor groove*.

Under low humidity/dehydrating conditions, duplex DNA will undergo a structural transition from the B-form to the A-form helix (Saenger 1984), which is the same helical structure associated with duplex ► RNA. The A-form helix is also right handed but with a helical repeat of approximately 11 base pairs per helical turn. The width and depth of the major and minor grooves of the A-form helix also differ significantly from the B-form helix.

DNA Coding of Proteins

The genetic information that codes for the amino acid sequence of a particular protein is *transcribed* from a DNA polymer by a DNA-directed RNA polymerase into messenger RNA (or mRNA). The information contained in the mRNA is then *translated* into a protein by the ► ribosome, tRNA molecules, and other proteins necessary for protein synthesis and the overall process of translation (Kornberg 2007).

The transcription of many genes in eukaryotic cells and bacteria is regulated by the binding of proteins known as *activators* and *transcription factors* to specific DNA sequences that are located “upstream” from the protein-coding region of a gene (Kornberg 2007). These gene-regulating proteins often recognize their target sequence through complementary hydrogen-bonding interactions between amino acid side chains and the edges of the nucleobases that are accessible in the major and minor grooves of duplex DNA. The major groove appears to be the preferred groove for sequence recognition by DNA-binding proteins due to the greater dissimilarity between the pattern of hydrogen donor and acceptor groups of the major groove base edges, in comparison to the minor groove (Seeman et al. 1976). Some transcription factors are able to differentiate between similar DNA sequences without direct contact between the protein and the DNA bases that differ between two otherwise identical DNA sequences. Such protein-DNA recognition is referred to as *indirect readout* and can have its physical origins in the flexibility of a nucleic acid sequence, water-

DNA, Fig. 2 A space-filling model of a 12 base-pair duplex of B-form DNA. (*Left*) The model orientated such that reader is looking into the major groove at the midpoint of the duplex. (*Right*) The same model, but orientated such that the reader is looking into the minor groove at the midpoint of the duplex. Backbone atoms are shown in white, base carbon atoms in green, base nitrogen atoms in blue, and base oxygen atoms in red. For clarity, hydrogen atoms are not shown

mediated contacts, and sequence-specific cation localization (Watkins et al. 2010).

DNA Packaging and Supercoiling

The amount of DNA necessary for coding all aspects of a living organism has necessitated the evolution of highly efficient DNA packaging mechanisms. For example, the human **genome** contains almost three billion base pairs of DNA per haploid genome. If the DNA contained within the diploid genome of a human cell was fully extended, it would have a linear measurement of nearly 2 m. Given that the diameter of a typical human cell nucleus is around 2 μm , genomic DNA must be packaged in a highly condensed state. In eukaryotic cells, the packaging of DNA is accomplished by a group of evolutionarily conserved and positively charged proteins that form the histones, octomeric protein assemblies that are each wound by 145 base pairs of DNA (Luger et al. 1997).

The genomic DNA of bacterial cells is packaged by a combination of molecular and physical factors, including supercoiling, molecular crowding, polyamines, and protein binding (Zimmerman 2006). Supercoiling refers to the over twisting of a topologically constrained DNA duplex (a covalently closed circle of duplex DNA is the simplest example of a topologically constrained DNA molecule). Much like a rubber band that has been rolled and twisted, a supercoiled and topologically constrained DNA molecule will tend to collapse onto itself. Molecular crowding agents and positively charged polyamines also promote the collapse of DNA into a highly condensed state within bacterial cells by promoting the general phenomenon of DNA condensation (i.e., the propensity for DNA to interact with itself in preference to the surrounding solvent) (Bloomfield 1996). It appears that two highly covered bacterial proteins known as HU and IHF facilitate DNA packaging by promoting local bends in the DNA double helix (Sarkar et al. 2007).

DNA Triplexes and Quadruplexes

DNA double helix formed between a homopurine strand (i.e., only A and G nucleobases)

and a homopyrimidine strand (i.e., only T and C nucleobases) under certain conditions (e.g., high salt or solutions containing Mg^{2+}) can form a triplex secondary structure with a third strand bound in the major groove (Frank-Kamenetskii and Mirkin 1995). This third strand forms the so-called Hoogsteen pairs with the major groove edges of the **purine bases** of the Watson-Crick duplex. There are two possible triplexes: pyrimidine triplexes, in which the third strand is composed only of pyrimidine nucleobases, and purine triplexes, in which the third strand is composed only of purine nucleobases. In the case of pyrimidine triplexes, the C nucleobases require protonation in order to form a Hoogsteen pair with the G bases. Because the pK_a of the C nucleobase is around 4.5, pyrimidine triplexes are most stable under slightly acidic conditions. Triplex-forming nucleotides have been the object of intensive study as potential therapeutic agents for the modulation of gene expression activity in vivo (Frank-Kamenetskii and Mirkin 1995).

G-rich DNA sequences (e.g., TGGGGT) are capable of forming four-stranded secondary structures called G-quadruplexes that are held together by G-tetrads in which the G nucleobases are in a planar, cyclic Hoogsteen hydrogen-bonded arrangement (Davis 2004). These structures are further stabilized by cation coordination by the guanine O6 carbonyl groups in the center of the G-tetrad. G-quadruplexes are potentially formed in vivo by a large number of G-rich DNA sequences within the human genome (Huppert and Balasubramanian 2007), which has been taken as evidence that G-quadruplexes are involved gene regulation.

DNA Interactions with Water and Cations

DNA-water and DNA-cation interactions are intimately associated with DNA structure. The high dielectric constant of water and cations screen the electrostatic repulsions that would exist between phosphate groups across the major and minor grooves. The screening of these repulsions by cations is reflected by the observed dependence of DNA duplex stability on the concentration of

salt in a solution, as well as the valency of the cation (e.g., monovalent versus divalent). As mentioned above, the role that hydration plays in regulating DNA helical structure is illustrated by the B- to A-form structural transition that occurs below 95% relative humidity.

Although it had long been postulated that DNA secondary structures have an absolute requirement for water, recent studies show that water is not the only media able to sustain native DNA structures. A new class of water-free deep eutectic solvents has been reported to sustain duplex, triplex, and G-quadruplex structures (Mamajanov et al. 2010).

The Origin of DNA

The discovery of catalytic RNA molecules, or ribozymes, and the ever-increasing evidence that RNA is the central polymer of life have created great enthusiasm for the hypothesis that RNA once carried out both the information storage needs are now satisfied by DNA as well as the catalytic tasks now accomplished by protein enzymes. There are additional reasons to suspect that RNA preceded DNA (Dworkin et al. 2003), including the appearance of ► [ribose](#) in model prebiotic reactions and the presumed lack of a prebiotic route to deoxyribose; activated ribonucleotides polymerize more readily than activated deoxyribonucleotides; the biosynthesis of deoxyribonucleotides is through ribonucleotides in extant life. Ribosides are subunits of many coenzymes, some of which have prebiotic syntheses.

The much greater chemical stability of DNA under conditions of neutral and basic pH, as compared to RNA, would have provided a strong evolutionary advantage for any organism that developed a means to synthesize DNA for use in long-term information storage. In contemporary life, ► [ribonucleotide](#) reductases are responsible for converting ribonucleotides into deoxyribonucleotides through a free radical-mediated process. The lack of known ribozymes that can carry out such reactions has been suggested as evidence that DNA must have appeared only after coded proteins were part of life (Dworkin et al. 2003). However, it has more recently been argued that

RNA could have synthesized DNA by a non-reductive mechanism (e.g., via aldol condensation chemistry), which could have allowed DNA to appear before coded proteins (Burton and Lehman 2009).

Basic Methodology

See ► [Nucleic Acids](#)

Applications

Genetic engineering, the artificial manipulation of genetic material for the production of natural and novel proteins, is a major branch of biotechnology that would not exist without our fundamental understanding of DNA structure and its use within living cells. Examples of genetic engineering applications in medicine include bacteria that produce human insulin and proteins for viral vaccines. In addition, DNA research has given rise to bioinformatics, a field that utilizes information technology, from data storage to DNA sequence analysis, to provide insights regarding biological evolution, from recent events to the root of the tree of life (Garrett and Grisham 2004). Finally, DNA is now routinely used in forensic science, with the help of PCR and bioinformatics, to identify suspects, as well as victims, and to provide what can be the most critical evidence in support of a conviction or acquittal.

Future Directions

Nucleic acid research is constantly moving forward with deeper insights into the forces that govern DNA structure and how DNA functions within living cells, as well as refinement of biotechnological applications. From the astrobiological perspective, the discovery that DNA secondary structure can be maintained in an anhydrous solvent (Mamajanov et al. 2010) supports the proposal that nucleic acids might have first evolved in nonaqueous or mixed aqueous-organic media.

Alteration

Definition

► **DNA** damage consists of chemical modifications of the deoxyribonucleic acid components that include alterations of the four main purine (adenine, guanine) and pyrimidine (cytosine, thymine) bases, the relatively minor 5-methylcytosine base and the 2-deoxyribose moiety. According to the damaging agents that may be endogenous

(reactive oxygen and nitrogen species such as hydroxyl radical, peroxynitrite, etc.) and exogenous (solar light, ionizing radiation, alkylating compounds, etc.), several classes of DNA lesions may be generated. These include single- and double-strand breaks, normal and oxidized abasic sites, single modified bases (oxidized lesions, alkylated adducts, addition products with reactive aldehyde arising from the breakdown of lipid peroxides, and 2-deoxyribose oxidation products), tandem modifications (intrastrand bipyrimidine photoproducts, vicinal oxidized bases), DNA-protein cross-links, interstrand cross-links, and clustered lesions (association of several oxidized bases, single- or double-strand breaks produced within one to two helix turns by several radiation-induced radical hits).

History

The discovery and characterization of *cis-syn* cyclobutane thymine dimer at the beginning of the 1960s, the main UVB- and UVA-mediated degradation product of isolated and cellular DNA, have provided a strong impetus to investigations in the fields of genotoxicity, mutagenesis, and ► **DNA repair**.

Overview

This entry focuses on the two main classes of DNA modifications that may be produced upon exposure of living systems to deleterious space conditions. These conditions comprise high vacuum, a wide range of temperature variations, and ionizing and UV radiations that have both galactic and solar origins (Nicholson et al. 2000). These effects include DNA photoproducts that are the main alterations generated upon exposure to solar extraterrestrial UV radiation of resistant microorganisms that may be carried in outer space. Under the latter conditions, the contribution of the second class of DNA damage that consists of radiation-induced degradation products involving mostly oxidative reactions is relatively minor.

However, the situation is different inside manned space vessels due to an efficient shielding against the UV radiation components involving the vacuum-UV ($140 < \lambda < 200$ nm), UVC ($200 < \lambda < 280$ nm), UVB ($280 < \lambda < 320$ nm), and UVA ($320 < \lambda < 400$ nm) photons. This protection is much more limited against high-charge (Z) and high-energy (E) (HZE) particles of galactic cosmic radiation (GCR) that, in addition to the HZE particles (1% of the nucleonic component), also include high-energy protons (87%) and α -particles (He ions) (12%) as well as electrons. Of concern are also solar particle radiations that are emitted during solar wind and erratic solar flares, consisting mostly of protons with very small amounts of α -particles and HZE ions (Durante and Cucinotta 2008).

Basic Methodology

Major progress has been made during the last two decades in the development of accurate and sensitive methods aimed at measuring photo- and radiation-induced damage to cellular DNA. This has benefited from the availability of new methodological approaches, including high-performance liquid chromatography coupled with electrospray ionization-tandem mass spectrometry detection (HPLC-ESI-MS/MS). Thus, the UV-induced DNA photoproducts that mostly consist of cyclobutane pyrimidine dimers (CPDs) and pyrimidine (6-4) pyrimidone photoproducts (6-4PPs) at the four main bipyrimidine sequences together with 5,6-dihydro-5-(α -thyminyl)-thymine, the so-called spore photoproduct (SP), can be measured by HPLC-MS/MS (Cadet and Douki 2010; Douki 2013). Polyclonal and monoclonal antibodies are also available for monitoring the formation of bipyrimidine photoproducts in cellular DNA and in tissue in a more semiquantitative way. HPLC-MS/MS is the method of choice for assessing the formation of single and clustered oxidatively generated base damage in cellular DNA at least under acute conditions of ionizing radiation exposure (Cadet et al. 2010). The modified version of the comet assay and the alkaline elution technique that both require the use of DNA

repair glycosylases to reveal classes of oxidatively generated damage such as oxidized bases and modified purine bases are suitable alternatives, although less specific than HPLC-MS/MS to deal with the detection of low amounts of radiation-induced DNA damage.

Key Research Findings

DNA Photoproducts

The UVC and UVB ► [photochemistry](#) of DNA that is triggered by the direct excitation of the bases is strongly dependent on the water content of the considered microorganisms, with two extreme situations that involve vegetative cells and bacterial spores.

Vegetative Cells

Dimerization of two adjacent pyrimidine bases is the overwhelming reaction induced upon exposure of DNA of vegetative cells to UVC and UVB photons, thus giving rise to two main types of photoproducts, namely, *cis-syn* cyclobutane pyrimidine dimers (CPDs) and pyrimidine (6-4) pyrimidone photoproducts (6-4PPs) (Fig. 1). The formation of CPDs involves a $[2 + 2]$ cycloaddition between the C5–C6 double bonds of the two adjacent pyrimidine bases. The generation of 6-4PPs is rationalized in terms of $[2 + 2]$.

Paternò-Büchi cycloaddition between the C5–C6 double bond of the 5'-end pyrimidine to either the C4 carbonyl of a thymine or the imine group of a cytosine in a suitable tautomeric form (Cadet and Vigny 1990; Taylor 1994). The efficiency of bipyrimidine photoproduct formation and the relative yield of CPDs and 6-4PPs are strongly dependent on the primary DNA sequence. Another striking feature is the efficient hydrolytic deamination of cytosine residues in either CPDs or at the 5'-end of 6-4PPs that leads to the formation of mutagenic uracil derivatives. One may add that UVA is able to induce CPDs through a direct excitation mechanism (Banyasz et al. 2011) with an efficiency that is higher than the generation of 8-oxo-7,8-dihydro-2'-deoxyguanosine (8-oxodGuo) (Cadet et al. 2009) that mostly arises from singlet oxygen oxidation of 2'-deoxyguanosine (Cadet et al. 2017).

DNA Damage,

Fig. 1 Photo- and radiation-induced damage in DNA: UVB-induced bipyrimidine photoproducts upon photoexcitation and radiation-induced base and 2-deoxyribose degradation products by hydroxyl radical ($\cdot\text{OH}$) and one-electron oxidation (ionization)

Bacterial Spores

The spectrum of DNA photoproducts in UVC- or UVB-irradiated bacterial spores is very different from what is observed in vegetative cells. Thus, the spore photoproduct (SP) that is another bithymine lesion is formed almost exclusively at the expense of CPDs and 6-4PPs in *Bacillus subtilis* spores (Cadet and Douki 2010). The pronounced changes in DNA photoreactivity have been accounted for by notable structural modifications of DNA molecules that were shown to adopt an A-like conformation. This was found to result from the binding of small acid-soluble proteins (SASP) in a dehydrated environment that is maintained by the presence of a high concentration of calcium dipicolinate (Ca-DPA). It was also shown that Ca-DPA is able to photosensitize the UVC-mediated formation of SP while protecting DNA against the damaging effects of UVB and UVA radiations (Cadet and Douki 2010). It may be added that CPDs and 6-4PPs are formed in significant amounts in spores that lack either

SASP or Ca-DPA, showing the major role played by the latter molecules in the generation of SP.

Radiation-Induced DNA Damage

The molecular effects of ionizing radiation on cellular DNA may be rationalized in terms of indirect effects through the generation of hydroxyl radical ($\cdot\text{OH}$), the product of water molecule radiolysis (Fig. 1), and direct interaction with the genetic material that leads to ionization of the bases and the 2-deoxyribose moiety (von Sonntag 1987). An important aspect to be considered in the mode of action of ionizing radiation is the multiplicity of radical and excitation hits that follow the energy deposition (Goodhead 1994). As a result, clustered damage, initially called “multiply damage,” consisting of several lesions (modified bases, abasic sites, single-, and double-strand breaks), may be generated within one or two helix turns. It may be added that the complexity of the clustered DNA damage increases with the ► **linear energy transfer (LET)** value of ionizing

DNA Damage, Fig. 2 Radiation-induced formation of 8-oxo-7,8-dihydro-2'-deoxyguanosine (8-oxodGuo) and *N*(2-deoxy- β -D-*erythro*-pentofuranosyl)-2,6-diamino-4-

hydroxy-5-formamidopyrimidine (FapydGuo) as the result of either $\cdot OH$ addition or electron abstraction

radiation and heavy particles. This is particularly of concern for space-ionizing radiation that consists of high-energy protons and densely ionizing high-LET HZE particles ranging from helium to uranium, whereas terrestrial radiation is represented mostly by low-LET photons (X-, β -, or γ -rays) (Durante and Cucinotta 2008).

$\cdot OH$ and One-Electron Oxidation Products as One-Hit Lesions

A large body of information is available on the $\cdot OH$ and one-electron oxidation of the purine and pyrimidine bases of DNA, thanks to comprehensive and detailed studies on model compounds Cadet et al. 2009; Wagner and Cadet 2010). Thus, the 4 *cis* and *trans* diastereomers of 5,6-dihydroxy-5,6-dihydrothymidine, 5-(hydroxymethyl)-2'-deoxyuridine, and 5-formyl-2'-deoxyuridine have been characterized as the main $\cdot OH$ -mediated degradation products of thymidine in cellular DNA (Cadet et al. 2008). Other pyrimidine base oxidation products including 5-hydroxy-5-methylhydantoin, 5-hydroxyhydantoin, 1-carbamoyl-4,5-dihydroxy-2-oxoimidazolidine, 5-hydroxymethylcytosine, and 5-formylcytosine have been identified in gamma-irradiated human cells (Madugundu et al. 2014). In addition, 8-oxo-7,8-dihydro-2'-deoxyguanosine (8-oxodGuo) and 2,6-diamino-4-hydroxy-5-formamidopyrimidine (Fig. 2) have been shown to arise from one-electron oxidation

and one-electron reduction, respectively, of 8-hydroxy-7,8-dihydroguanyl radical, the initial $\cdot OH$ addition product to guanine (Cadet et al. 2010). Similar degradation products are generated by $\cdot OH$ addition to adenine, however, with an efficiency that is about tenfold lower than for guanine degradation products. One-electron oxidation of nucleobases in cells gives rise to the same pattern of degradation products as those induced by $\cdot OH$. However, one may note a different product distribution since 8-oxodGuo is formed predominantly upon ionization of the bases as the result of the positive hole migration along the DNA chain with preferential trapping of the radical cation at guanine sites (Genereux and Barton 2010; Kanvah et al. 2010). It is well documented that DNA single-strand breaks (SSBs) are generated by $\cdot OH$ -mediated hydrogen abstraction from the 2-deoxyribose moiety (von Sonntag 2006; Dedon 2008). Ionization reactions are also likely to be involved in the formation of SSBs although there is still a lack of mechanistic information.

Specific Radiation-Induced Clustered Damage

DNA double-strand breaks (DSBs) that consist of two closely spaced and opposed single-strand breaks (SSBs) separated by less than 15 base pairs are the most representative radiation-induced DNA-clustered damage. It has been

predicted by Monte Carlo calculations that the frequency of complex DSBs that contain at least one additional nick/or modified base increases up to 70% for 2 MeV particles, while the proportion was only 20% for low-LET 4.5 keV electrons. Experimental support for the induction of a higher density of DSBs with the increase in LET of incident HZE particles was provided by the observation of a larger frequency of fluorescent γ -H2AX foci (i.e., 1 of the eukaryotic histones that become phosphorylated on serine 139 as a reaction to DNA DSBs formation). It has also been shown that the DSBs generated with high-LET radiation are more difficult to be repaired likely due to an increase in the complexity of the clustered lesions.

A second class of complex DNA damage consists of non-double-strand break-clustered damage that may comprise at least one-strand break together with one or several base lesions and/or apurinic sites on the two complementary DNA strands within one or two DNA helix turns (Hada and Georgakilas 2008). Attempts have been made using a DNA repair-based assay to monitor the formation of these lesions. However, it was found that the yield of clustered lesions, thus measured, is only slightly lower to those of single oxidized bases in irradiated cells, a rather surprising finding. At this point, it may be stressed that further work is required to better assess the formation of clustered DNA modifications.

Applications

The measurement of CPDs, 6-4PPS, and SP photoproducts has been made in the DNA of several microorganisms allowing detailed studies of their repair. The yields of bipyrimidine photoproducts vary according to the microorganisms due to the presence in some cases of photoprotective compounds and differences in the membrane composition. One may also note that the radiation-induced formation of 8-oxodGuo in cellular DNA was found to decrease with the increase in LET of the radiation. This is indirectly indicative of the major deleterious role played by complex clustered DNA damage in ► [radiation biology](#).

Future Directions

Efforts should be made to better ascertain the effects of vacuum-UV light on the DNA of resistant microorganisms including bacterial spores when exposed to outer space conditions in terms of photoproduct distribution. Another major topic to be further investigated concerns the detection and quantification of radiation-induced clustered damage, whose identification remains a challenging issue due to the complexity of the analytical problem thus addressed and the oneness of each of the damage.

DNA Damage Correction

► DNA Repair

DNA Polymerase

Juli Peretó

Institut Cavanilles de Biodiversitat i Biologia Evolutiva, Universitat de València, València, Spain

Synonyms

DNA- (or RNA-)dependent DNA polymerase; DNA replicase; Klenow fragment

Definition

DNA polymerase is an enzyme which catalyzes the addition of a deoxynucleoside triphosphate to the 3' end of a DNA strand using a template. The systematic name of this enzymatic activity is deoxynucleoside-triphosphate:DNA deoxynucleotidyl transferase and the catalyzed reaction can be represented as

DNA-directed DNA polymerases (EC 2.7.7.7) use DNA templates, whereas RNA-directed DNA polymerases (EC 2.7.7.49), also known as reverse transcriptases, use RNA templates. These enzymes cannot initiate a chain de novo and require a primer, which may be DNA or RNA. Some DNA-directed DNA polymerases have acquired proofreading mechanisms through a 3'–5' exonuclease activity.

History

DNA polymerase I from *Escherichia coli* was discovered by Arthur Kornberg in 1956

(awarded with the Nobel Prize in Physiology or Medicine in 1959). Howard Temin and David Baltimore independently discovered viral reverse transcriptase in 1970 (both scientists shared the Nobel Prize in Physiology or Medicine in 1975).

DNA damage · DNA, repair of damage

Synonyms

[DNA damage correction](#)

Definition

DNA repair refers to a collection of processes by which a cell identifies and corrects damage to the DNA molecule(s) that encode its genetic information.

History

The discovery and early history of DNA repair has been reviewed recently (Friedberg 2008 and references therein).

Overview

Deoxyribonucleic acid (DNA) is the molecule that stores the genetic instructions used by all known living organisms and some viruses (other viruses use ribonucleic acid – RNA – as their genetic material). Successful propagation of life is therefore dependent upon the faithful copying of the information encoded in the sequence of DNA bases in a process called replication.

In the context of astrobiology, DNA can be damaged by exposure to environmental factors such as heat, ultraviolet or ionizing radiation, extreme vacuum, desiccation, various toxic chemicals, or oxidizing agents. DNA can also be damaged as a result of normal metabolic processes occurring within cells. ► [DNA damage](#) can either: (1) block the progress of replication by the ► [enzyme](#) DNA polymerase, leading to cell death; or (2) lead to the incorporation of incorrect bases during replication, resulting in mutations.

In order to maintain the integrity of the structure and base sequence in DNA, the cell employs a number of enzymatic DNA repair processes to specifically recognize and correct damage to DNA or errors of base incorporation. Most of the DNA repair pathways described below have been shown to be important for microbial survival to exposure to outer space or other extreme environments such as the surface of Mars (Nicholson et al. 2005; Moeller et al. 2007):

- Certain types of DNA damage can be repaired by *direct reversal* using enzymes that recognize the specific type of damage. Photoreactivation is a light-dependent DNA repair mechanism, in which the UV-induced *cis-syn* cyclobutane pyrimidine dimers (CPDs) are enzymatically monomerized by a photolyase (Friedberg et al. 2006). UV-irradiated bacterial spores accumulate a spore-specific thymine

dimer, spore photoproduct (SP), that can be directly reversed to two thymines using the enzyme SP lyase (Nicholson et al. 2000).

- *Excision repair* pathways are used to correct a number of different types of damage occurring on only one of the two DNA strands. In general, damage-specific enzymes excise the damaged region and the correct sequence is restored by a specific repair DNA polymerase using the opposite, undamaged strand as a template. Examples are ► [nucleotide](#) excision repair, base excision repair, and methyl-directed mismatch repair (Friedberg et al. 2006).
- DNA damage can also be corrected by homologous ► [recombination](#) repair. In this pathway, when DNA is being actively replicated, pieces of damaged DNA can be swapped for undamaged DNA originating from the undamaged daughter strand, using a series of specific recombination (Rec) enzymes (Friedberg et al. 2006).
- Double strand breaks (DSB) can be formed in DNA by ionizing radiation or extreme desiccation. DSB are especially lethal because they disrupt the integrity of the DNA molecule. DSB are repaired in bacteria by a pathway called non-homologous end joining (NHEJ), in which the broken ends are rejoined by a specific DNA ligase. NHEJ has been shown to be important in the survival of spores to various types of ionizing radiation and high-energy particle bombardment (Moeller et al. 2007).

DNA Sequencing

Carlos Briones

Centro de Astrobiología (CSIC/INTA), Consejo Superior de Investigaciones Científicas, Madrid, Spain

Synonyms

[Gene sequencing](#); [Sequencing](#)

Definition

- [DNA](#) sequencing is the process by which the order of ► [nucleotides](#) in a DNA molecule is determined. The first DNA sequencing method – set up by A. Maxam and W. Gilbert in the decade of the 1970s – was based on the controlled chemical breakage at one or two of the four

► [nucleotides](#). In parallel, F. Sanger developed an alternative system which relies on the abortive synthesis of complementary DNA strains, thanks to the use of dideoxynucleotide triphosphates – also called “dideoxys” – as chain terminators. In both methods, the fragments are separated and identified by ► [electrophoresis](#). The Sanger method for DNA sequencing gave rise to automatic DNA sequencers based on capillary electrophoresis, thus triggering the explosion of ► [genome](#) sequencing projects in the 1990s. Since 2005, a number of “next-generation” techniques have been released, producing a spectacular increase in sequencing speed together with a drastic reduction in the cost. They include the so-called pyrosequencing, sequencing by synthesis, and sequencing by ligation. Later on, the current “third-generation” techniques allow the fast and reliable sequencing of single DNA molecules. This is widely regarded as the future of sequencing, since single-molecule approaches do not require the DNA to be previously amplified.

CNRS UMR8079 Université Paris-Sud 11, Paris,
Orsay Cedex, France

Keywords

Archaea · Bacteria · Eukarya

Synonyms

[Empire](#); [Primary kingdom](#); [Superkingdom](#)

Definition

Domain is the highest taxonomic rank in the hierarchical biological classification system, above the kingdom level. There are three domains of life, the ► [Archaea](#), the ► [Bacteria](#), and the ► [Eukarya](#). Organisms from Archaea and Bacteria have a prokaryotic ► [cell](#) structure, whereas organisms from the domain Eukarya (eukaryotes) encompass cells with a nucleus confining the genetic material from the cytoplasm.

Overview

The term “domain” was introduced by Carl R. Woese et al. (1990) together with the proposal of a natural classification system for all life on Earth, including microorganisms, which had previously escaped any attempt of classification based on evolutionary relationships (Woese et al. 1990). Woese’s proposal to class life in three major phylogenetic domains was an attempt to institutionalize the three major phylogenetic groupings of organisms that he had previously observed and defined (Woese and Fox 1977) based on differences in the small subunit ribosomal RNA, a macromolecule chosen as an ideal phylogenetic marker due to its universality, degree of conservation, and essential function. The three-domain classification system was proposed as an alternative to other life classification systems in use at that time, such as the traditional prokaryote-eukaryote division or the five-kingdom system (Monera, Protista, Fungi, Plantae, and Animalia) proposed by R. Whittaker in 1969. The three-domain classification based on ribosomal RNAs was received with skepticism by most biologists at that time, who were not ready to accept that the evolutionary information stored in one single macromolecule had more weight than other, phenotypic, characters. O. Kandler and his German school provided additional features that distinguished radically the two prokaryotic groups (Archaea and Bacteria)

including cell wall biochemistry and the presence of eukaryotic-like RNA polymerases in Archaea. The marked differences between archaea and bacteria have been widely demonstrated since then, thanks, among others, to the comparison of full genome sequences. The classification of life in three phylogenetic domains is well established today. It does not imply the demise of the prokaryote-eukaryote dichotomy at the structural level, which is an empirical reality. Therefore, there are two types of cells from a structural point of view, but three domains of life from a phylogenetic point of view.

Doppler Shift,

Fig. 1 Diagram illustrating how the measured wavelength of a wave emitted by a moving source changes, depending on the direction of the movement with respect to the observer

Doppler Shift

Daniel Rouan

LESIA, Observatoire Paris-Site de Meudon,
Meudon, France

Definition

The Doppler shift is the change in frequency and wavelength of a propagating wave (acoustic, electromagnetic, etc.), caused by the movement of the source emitting the wave relative to the observer. This effect is named after the Austrian physicist Christian Doppler who proposed it in 1842. In France, the effect is currently called Doppler–Fizeau, because the French physicist Hippolyte Fizeau proposed it for electromagnetic waves in 1848. If the source is moving away from the observer, the wavelength appears stretched while frequencies are shifted toward lower values, and if the source is approaching, the wavelength appears compressed and frequencies shifted toward higher values. In the case of light, the effect is called redshift (receding source) and blueshift (approaching source), respectively. This effect is of great importance in astronomy because it allows direct determination of the radial speed of celestial objects and of the distance of remote galaxies (because of the expansion of the Universe). It provides the basis for the most productive method for detection of exoplanets, the so-called ► [radial velocity](#) method. The relative amount of wavelength

change when the velocity is not close to the speed of light is given by the relation $\Delta\lambda/\lambda = v/c$, where v is the relative velocity, c is the velocity of the wave (e.g., speed of light), λ is the wavelength, and $\Delta\lambda$, the change in wavelength (Fig. 1).

Dormant State

Felipe Gomez

Centro de Astrobiología (CSIC/INTA), Instituto Nacional de Técnica Aeroespacial, Torrejón de Ardoz, Madrid, Spain

Definition

Dormant state refers to a reduced metabolic activity phase adopted as strategy to escape stressful conditions and/or save energy. It refers to a latent but capable to be active state. The adverse weather

conditions (low temperature in winter time, etc...) drive a plant or animal population to reduce their metabolic activity in order to preserve themselves avoiding frosting conditions. The spore state of sporulating Gram-positive bacteria is considered a dormant state of the bacterium.

Double Helix

Henderson James Cleaves II

Earth-Life Science Institute (ELSI), Tokyo Institute of Technology, Tokyo, Japan

Blue Marble Space Institute of Science, Washington, DC, USA

Center for Chemical Evolution, Georgia Institute of Technology, Atlanta, GA, USA

Definition

A double helix consists of two congruent helices with the same axis, differing by their translation along the axis. In molecular biology, complementary double-stranded ► [DNA](#) typically adopts a double-helical structure. The DNA double helix

Double Helix, Fig. 1 Three double-helix structures adopted by double-stranded DNA under different physiological conditions

can be (from left to right in Fig. 1) of the A- or B-form, which are right-handed but differ from each other in the distance required to make a complete helical turn or of the Z-form, which is left-handed. The double-helix model of DNA structure was published in *Nature* by Watson and Crick in 1953. DNA is typically found in the B-form, while double-stranded ► **RNA** typically adopts the A-form.

DPANN, Archaea

Ricardo Amils

Departamento de Biología Molecular, Centro de Biología Molecular Severo Ochoa, Universidad Autónoma de Madrid, Madrid, Spain

Definition

DPANN is a superphylum of the domain Archaea also named Nanoarchaea or ultrasmall archaea due to their small size. The name of the group is the acronym formed by the initials of the first discovered phyla: **D**iapherotrites, **P**arvarchaeota, **A**enigmarchaeota, **N**anoarchaeota, and **N**ano-haloarchaeota. More recently identified archaea have been placed within this superphylum. They are characterized by their small size ($<0.1 \mu\text{m}^3$) and small genome that limit their metabolic capacities. These are similar properties than the ultrasmall bacteria (CPR). Although many members of this group depend on symbiotic relationship with other organisms, some maintain a cell-free life status using mainly fermentation for the generation of cellular energy. Mostly they have been identified in anaerobic extreme environments at

high temperature, acidic pH, or high salt concentrations, although some members have been detected in less extreme environments like lake and marine sediments. The monophyletic status of DPANN is not well established yet and some phylogenetic analysis place them as members of the Euryarchaeota.

Drake Equation

Leticia Carigi

Instituto de Astronomía, Universidad Nacional Autónoma de México, Ciudad de México, Mexico

Synonyms

Green bank equation

Definition

The Drake equation estimates the number of communicating extraterrestrial civilizations that might exist within the Milky Way today. This formula was proposed by Frank Drake in 1961 to organize the knowledge, at that time, about the formation and evolution of extraterrestrial life.

Overview

The original Drake equation gives the number (N) of civilizations in the Galaxy that are able to communicate through electromagnetic waves. That formula is written as the product of seven terms, as follows:

$$(N = R \times f_p \times n_e \times f_l \times f_i \times f_c \times L),$$

where (1) R is the rate of formation of stars suitable for life, that is, solar-type stars, in units of stars per year; (2) f_p is the fraction of suitable stars surrounded by planetary systems; (3) n_e is the number of planets suitable for life in a given planetary system, that is, the number of planets located within the habitable zone; (4) f_l is the fraction of habitable planets, within that zone, where basic life appears; (5) f_i is the fraction of planets on which basic life evolves into intelligent life; (6) f_c is the fraction of planets on which intelligent life develops a sufficiently high technology capability to broadcast signals of its existence out into the Galaxy; and (7) L is the lifetime of such a technological civilization emitting detectable signals into space.

The R factor is best understood in the equation due to the vast body of astronomical data available; f_p and n_e factors can be estimated with some degree of certainty using the properties of exoplanets detected so far. However, the remaining factors are unknown at present since we do not know any extraterrestrial life form or civilization. In particular, the L factor is the least known in the formula, because we have no idea even how long our civilization will last, and at the same time, is

the most determining factor in the Drake Equation. Thus, depending on whether one adopts the pessimistic or the optimistic point of view, a civilization may last 10 years or 100,000 years; he/she may obtain $N = 1$ or $N = 10,000$, respectively, indicating that we are either almost alone in the Milky Way (see Fermi Paradox) or, on the contrary, in the Galaxy there exist an abundance of extraterrestrial civilizations that are yet to be detected.

An important problem with the Drake equation is its incompleteness since the formula omits important factors such as possible interstellar colonization, the habitable planets or moons in stars unlike our Sun, the change of the habitable zone with the evolution of a star, the metallicity requirements for the formation of earthlike planets, etc. Since 1961, according to the new knowledge of Astrobiology, new factors have been added and the equation has been used as a basis for more general calculations of the possibility of detecting life in our galaxy.

Dresser Formation, Traces of Life

Rogers C. C. Buntin and Nora Noffke
Old Dominion University, Norfolk, VA, USA

Keywords

Dresser Formation · Warrawoona Group · Pilbara · Archean · MISS · Microbial mat · Stromatolite · Microbialite · Biosignature, early life, extraterrestrial life, Mars

Acronyms

MISS Microbially induced sedimentary structures

Overview

The Archean Dresser Formation (~3.48 Ga) crops out at several localities in the North Pole Dome, Pilbara, Western Australia (Fig. 1). A wide range of stromatolites, MISS, microfossils, mat fabrics, and biosignatures are preserved within hydrothermal dykes, barite mounds, siliciclastic deposits, and siliceous and ferruginous carbonates (Buick and Dunlop 1990) (Fig. 2). The spatial relation between stromatolites and biogenic carbon and sulfur isotopes suggests the presence of hyperthermophilic microbes (Ueno et al. 2008; Duda et al. 2018). Stromatolites and MISS aid reconstructions of the sedimentary setting because their morphologies are highly mediated by both biotic and environmental factors. The microbial structures also include abundant mat fabrics that allow insight into the evolutionary history of the Prokaryota. The Dresser Formation also offers the opportunity to study early Archean seawater chemistry. This review gives an overview on evidence of microbial life in the Dresser Formation.

Geologic setting The Dresser Formation (*ca.* 3.48 Ga) of the Warrawoona Group (Fig. 1c) is restricted to a ~25km² area in the North Pole

Dome of the East Pilbara granite greenstone terrane of Western Australia (Van Kranendonk et al. 2008; Noffke et al. 2013). The primary lithologies of the Dresser Formation (Fig. 1d) include: (i) komatiitic metabasalt transected by silica-rich veins; (ii) fossiliferous, interbedded chert and barite; and (iii) pillow basalts with interbedded cherts and diabase (Buick and Dunlop 1990; Philippot et al. 2009; Noffke et al. 2013). Chert-barite veins within the lowermost basal and komatiitic basalts are considered syngenetic, terminating at the chert-barite unit and occasionally found as allochthonous clasts in the overlying lithologies (Van Kranendonk 2006; Baumgartner et al. 2020). The fossiliferous chert-barite unit (North Pole Chert Member) ranges in thickness from 2–120 m and is a hydrothermally altered sedimentary succession composed of volcanoclastic sandstones and mudstones, as well as chemically derived carbonate-rich, banded and peloidal cherts, barite, and gypsiferous and dolomitic mudstones (Buick and Dunlop 1990; Baumgartner et al. 2020). Biosignatures found within the sedimentary succession include: stromatolites, MISS, ooids and peloids, a wide range of organic microfossils and mat fabrics, as well as fractionated carbon and sulfur isotopes (Dunlop et al. 1978; Buick and Dunlop 1990; Noffke et al. 2013; Djokic et al. 2017). Paleoenvironmental reconstructions of the chert-barite suggest deposition within either an enclosed volcanic caldera or an evaporitic lagoon, both influenced by syndepositional hydrothermal circulation (Groves et al. 1981; Buick and Dunlop 1990; Nijman et al. 1998; Van Kranendonk 2006; Van Kranendonk et al. 2008).

Basic Methodology

A geological field survey and stratigraphic logging gains an overview on the paleosetting recorded by the rock succession. Samples are collected, where permitted by the Geological Survey of Western Australia. Epoxy-hardened thin-sections are used to identify microscopic structures including organic microfossils and mat fabrics, as well as microsequences, sinoidal

Dresser Formation, Traces of Life, Fig. 1 Location of the Dresser Formation: (a) The stratigraphic rock succession crops out in the Pilbara Craton, Western Australia. (b) The Dresser Formation forms a roughly circular structure

in the North Pole Dome Area. (c) Stratigraphy of the Warrawoona Group. (d) Simplified stratigraphic log of the Dresser Formation. (After Van Kranendonk 2006; Van Kranendonk et al. 2008)

structures, fenestrate porosity, and others. Mat fabrics includes fossilized coccoids, filaments, and extracellular polymeric substances (EPS), permineralized or replaced *in situ* (Amrawik 1992; Noffke 2010). Petrographic analyses of microbial structures allow statistical analyses of such micromorphologies (Noffke 2010) and the

classification of various microfossil morphology (Grey and Sugitani 2009; Baumgartner et al. 2020). Chemical etching of thin sections allows exposure of organic matter and prepares samples for analyses of organic matter and isotope mapping like Raman spectroscopy (Grey and Sugitani 2009; Baumgartner et al. 2020). Gas-

Dresser Formation, Traces of Life, Fig. 2 Microbially induced sedimentary structures in the 3.48 Ga Dresser Formation, Pilbara, Western Australia: (a) Classical site of wrinkly in situ preserved microbial mat and a stromatolite; scale 15 cm. (b) Stromatolites; scale 10 cm.

(c) Microbial mat chips; scale 1 cm. (d) Wrinkle structure; scale: 15 cm. (e) Vertical section through ca. 3.4 Ga old biofilms possibly of chemoautotrophic microbes, thin-section view. Image provided by Frances Westall; scale ca. 100 μm

chromatographic mass spectrometry and catalytic hydropyrolysis (HyPy) allows the liberation of non-extractable hydrocarbons (i.e., kerogen) to determine carbon fixation via microbial activity (Marshall et al. 2007; Duda et al. 2018; Lepot 2020).

Key Research Findings

Stromatolites Van Kranendonk (2006) and Van Kranendonk et al. (2008) and Hickman-Lewis et al. (2019) identified numerous stromatolites in the chert-barite unit including biolaminites,

domical, stratiform, and coniform morphologies (Fig. 2). Abundant biolaminites, domical stromatolites, and local stratiform morphologies are recognized in the lowermost chert and are associated with barite and interlaminated gray and white cherts (Van Kranendonk 2006). Layers including pyrite crystals occur directly above the lowermost metabasalt and are characterized by millimeter-scale laminae of FeS₂ and minor contributions of carbonate, chert, barite, and sphalerite (Van Kranendonk et al. 2008). Current rippled micrite higher in the stratigraphy include stratiform and conical stromatolites (Van Kranendonk 2006).

The biogenicity of laminites in the Dresser Formation is supported by their relationship to barite crystals. In hydrothermally derived cherts, laminates have no association with barite crystals. Avoidance of barite suggests growth occurred contemporaneous to hydrothermal fluid circulation. However, similar structures can form abiotically in hydrothermal vents as primary chemical precipitates (Hannington and Scott 1988; McLoughlin et al. 2008; Lepot 2020). If biogenic in origin, the morphologic diversities of stromatolites and their varying lithofacies associations suggest high diversity and niche exploitation by bacteria by 3.48 Ga. Van Kranendonk (2006) interpreted stratiform and domical stromatolites to have been produced by subaqueous chemoautotrophic extremophiles. Similar morphologies are associated with hydrothermal vents in modern shallow calderas, where laminated kerogen occurs in siliceous veins (Ueno et al. 2004). Photoautotrophic bacteria are interpreted to have produced domical stromatolites within a shallow marine carbonate platform setting (Van Kranendonk 2006).

Microbially induced sedimentary structures A great variety of MISS occurs in the Dresser stratification (Noffke et al. 2013). Sinoidal structures are drapes or laminations atop ripple cross-stratification. The laminae show regularly shaped and spaced tufts composed of pyrite with minor carbonaceous material preserved within a silica-rich rock bed. Sinoidal structures are identified alongside stromatolites described by Buick and Dunlop 1990 (e.g., by Van Kranendonk 2006;

Van Kranendonk et al. 2008) and interpreted to have formed in a subtidal environment.

Microbial mat chips and roll-up structures (Fig. 2) are also identified in two facies zones (Noffke et al. 2013). These chips are of 0.1–3.5 cm diameters and up to 0.4 cm thicknesses. Some chips are wavy or even rolled up, which documents their former ductile properties. This ductile behavior and the co-occurrence with biolaminites suggest biogenicity of these structures. Microbial mat chips and roll-ups are interpreted to occur in intertidal and lagoonal facies (Noffke et al. 2013).

Erosional remnants and pockets are well preserved on widely exposed bedding planes with 1–3 cm differences in elevation between remnants and pockets. Slope angles ranging between 15–90° yield modification index (MOD-I) values between 0.18–0.33. Index values produced by the MOD-I indicate the degree of microbial influence during formation of erosional pockets and remnants. Values are calculated by considering the area of a mat covered surface within a given area, the slope angle between the erosional pocket and remnant, and the thickness of a microbial mat over levelled ripple marks within ripple valleys. Continuous values between 0–1 indicate no microbial influence to maximum microbial influence, respectively.

Polygonal oscillation cracks described by Noffke et al. (2013) are 3–10 cm wide cracks defining polygons. Each polygon has a dent or hole at its center. Such a crack pattern derives from lateral shrinking and expanding of mat polygons responding to alternating humid and arid conditions in a seasonal climate (Noffke 2010). The holes in the polygon centers indicate rupturing of the ancient mat due to increasing gas pressure (Noffke et al. 2013).

A domical stromatolite described by Walter et al. (1980) from the Dresser Formation contains a hollow cavity that may reflect a preserved gas dome (Amrawik 1992). Given their modern distribution in sabkha-like settings along the mean high water line, polygonal oscillation cracks and gas domes are interpreted by Noffke et al. (2013) to have formed in an upper supratidal zone.

Microfossils Archean-age microfossils display simple morphologies and sizes typical of younger Precambrian microfossils (Schopf et al. 2007). Biogenicity can be ascertained when structures in question were rapidly permineralized or even found in association with stromatolites (Amrawik 1992; Schopf et al. 2007). Carbonaceous spheroids found in the Dresser Formation occur in silicified carbonates and were first described by Dunlop et al. (1978). The authors interpreted five unique microfossil morphologies including solitary spheroids, spheroids with splits, paired spheroids, and chains of spheroids. However, these carbonaceous spheroids were later argued to possibly be abiogenic in origin (Schopf and Walter 1983; Buick and Dunlop 1990). Four additional filamentous microfossils were described by Amrawik et al. (Awramik et al. 1983; Awramik et al. 1988). The location (Awramik Locality A) of the horizon from which additionally collected microfossils derived is uncertain. Uncertainty of the stratigraphic position of these fossils had led to some controversy about the biogenicity of these structures (Buick 1991; Amrawik 1992). Wacey et al. (2018) demonstrated the similarities between spheroidal microfossils and permineralized fragments of vesicular volcanic glass.

Chemical Biosignatures Geochemical evidence for early life is derived from isotopes (i.e., sulfur, iron, nitrogen, and carbon) reflecting an ancient spectrum of original microbial metabolism. Fractionation of carbon isotopes by primary production of organic matter and oxidation of iron and sulfur takes place via anoxygenic photosynthesis and chemolithotrophy (Lepot 2020). In anaerobic environments, CO₂ is reduced with H₂ (either from decaying organic matter, hydrothermally sourced, or atmospheric) to produce CH₄ or C₂H₃O₂ by methanogenic and acetogenic bacteria, respectively (Lepot 2020). Sulfur isotope fractionations (³²S/³³S/³⁴S/³⁶S) can be used as an indicator of microbial activity, because relatively large depletions in ³⁴S are a marker of microbial sulfate reduction (Philippot et al. 2007; Ueno et al. 2008; Wacey et al. 2015; Lepot 2020). Pyrite from

microbial mats in the Dresser Formation is heavily depleted in ³⁶S with a steep Δ³⁶S/Δ³⁶S slope, suggesting polysulfide pyrite precursors were formed by the mixing of mass independent fractionated sulfur and sulfur derived from microbial reduction of seawater sulfate (Wacey et al. 2015).

Kerogen containing significant amount of ¹³C-depleted carbon was described by Ueno et al. (2004) from silica-rich dikes intruding into pillow basalts. They argue organic matter was produced *in situ* along fissures and hydrothermal vents by chemoautotrophs, such as methanogenic bacteria. Catalytic hydropyrolysis of kerogens derived from chert from the komatiitic basalt yielded alkanes with a sharp decrease in homologues beyond C₁₈. Comparison with alkanes derived from modern cyanobacteria biomass suggests kerogen found in the Dresser Formation is biological in origin (Duda et al. 2018). Findings of Duda et al. (2018) are consistent with other alkane size-distributions yielded in analyses of Proterozoic kerogen (Ueno et al. 2001) and in cyanobacterial biomasses (Marshall et al. 2007).

Barite microspherules described by Baumgartner et al. (2020) are associated with stromatolites and pyrite laminations in the lowermost carbonate of the North Pole Member (Van Kranendonk et al. 2008). A biogenic origin for the barite precipitation is suggested by the porous internal textures produced in modern studies that demonstrate the precipitation of spherulitic barite around amorphous material (i.e., EPS and cellular surfaces; Stevens et al. 2015; Torres-Crespo et al. 2015; and Baumgartner et al. 2020). Additionally, framboidal and spherulitic barite aggregates precipitate at modern cold seeps rich in organic matter and in association with sulfur-reducing bacteria (Stevens et al. 2015; Baumgartner et al. 2020). Sulfur isotope analysis of the Dresser Formation chert-barite unit and chert veins supports the presence of local sulfate-reducing microbial communities (i.e., large δ³⁴S fractionations and I δ³³S/δ³⁴S slopes expected from microbial activity) (Philippot et al. 2007, 2009; Ueno et al. 2008).

Future Directions

The overall consensus is that the spectrum of stromatolites, MISS, microfossils, and chemical biosignatures in the Dresser Formation is witness to flourishing life of great diversity already in the early Archean. Studies in such old rocks on Earth deliver the criteria necessary for the exploration of extraterrestrial life in missions to Mars and other terrestrial planets.

DTU Space, Denmark

Michel Viso
Innovaxiom, Paris, CX, France

Synonyms

- [Institut for Rumforskning og -teknologi](#);
- [National Space Institute, Denmark](#)

Definition

DTU Space, the conventional abbreviation for the National Space Institute at the Technical University of Denmark (DTU), was established in 2007 from the merger of several preexisting research groups and government laboratories, including the Danish Space Research Institute (DSRI). The DSRI had existed since the formation of the European Space Research Organization, which subsequently became the core of the European Space Agency (ESA). A key role for DTU Space is the development of instruments for the ESA Science Program, which enables Danish scientists to have access to scientific data from ESA missions. Another key national role is providing the research basis for a geodetic reference system for the kingdom of Denmark (Denmark itself, Greenland, and the Faroe Islands).

Dubiofossil

Emmanuelle J. Javaux
Early Life Traces & Evolution-Astrobiology,
University of Liège, Liège, Belgium

Definition

A dubiofossil is a problematic structure that looks like a ► [fossil](#) but whose biological origin is uncertain or ambiguous. Several physical and chemical processes may produce structures resembling biological structures. In the recent literature, scientists also use the terms “putative,” “possible,” “probable” to designate an increasing confidence in the biological origin (biogenicity) of a structure, molecule, or pattern, while “pseudofossil” is used for an unambiguous abiotic structure, molecule, or pattern. Detailed analyses and criteria of ► [biogenicity](#) have to be applied on the dubiofossils to move them to the category of fossils (biogenic or biological structures) or ► [pseudofossils](#) (abiogenic or non-biological structures). This requires also a good understanding of the physico-chemical conditions of formation and preservation of the structure (the geological context and taphonomy), and observations at several scales. This is a crucial point when looking for early traces of life on Earth or for extraterrestrial life.

Definition

Dust Devils are meteorological phenomena that have been detected in the atmospheres of ► [Earth](#) and ► [Mars](#). They are thermally driven atmospheric vortices that are filled with loose materials such as dust and sand. The vertical velocity is predominantly upward. Their size ranges with heights from a few meters (on Earth and Mars) to several kilometers (only on Mars) and from a few meters to hundreds of meters in diameter. The first images of Dust Devils in the Martian atmosphere were taken by the ► [Viking](#) orbiter.

Dust Grain

William M. Irvine
University of Massachusetts, Amherst, MA, USA

Synonyms

[Interstellar grain](#)

Definition

The small solid particles present in the interstellar medium are called dust grains or often simply either dust or grains. Most of them are only a few tenths of a μm in size. They consist of silicates and carbon compounds, coated in the coldest regions with icy mantles. They represent 1–2% of the mass of interstellar clouds. Their origin and composition are discussed in *interstellar dust*.

Dwarf Planet

Tilman Spohn
International Space Science Institute, Bern,
Switzerland

Definition

A dwarf planet according to the IAU (International Astronomical Union) Resolutions 5 and 6 (Resolution GA26-5-6, passed in 2006) is a celestial body of intermediate size, which orbits the Sun, is not a satellite, has not cleared the neighborhood around its orbit, and has sufficient mass for its self-gravity to maintain a nearly round shape. To date five dwarf planets have been

identified, namely, the asteroid ► [Ceres](#), ► [Pluto](#), Eris, Makemake, and Haumea, the latter three being ► [trans-Neptunian objects](#).

Definition

Ejnar Hertzsprung and Henry Norris Russell independently found the existence of stars with the same spectral type but different luminosities. Since the luminosity satisfies the relationship $L \sim R^2 T^4$, the most luminous ones must be larger than the dimmer ones and they coined the terms giant and dwarf stars. Based on the existing differences in the spectral features of stars with the same type, William W. Morgan and Phillip C. Keenan, from Yerkes Observatory, introduced the so-called “luminosity class” represented by a Roman number. One of these classes, the V one, was the Main-Sequence class, also known as dwarfs since normal stars at this stage have the minimum radius. However, since main-sequence blue stars have very large masses and radii, the term “dwarf star” is at present usually used to design main sequence stars with a mass equal or smaller than the Sun. For instance solar-like stars

are yellow dwarfs, and main-sequence M stars are red dwarfs. The term dwarf is also used in other stars having completely different properties but sharing a small size, like white dwarfs or brown dwarfs.

Acronyms

DKS

Definition

A stability kind associated with physicochemical systems maintained in a cyclical nonequilibrium dynamic state through a continual supply of energy. Such cyclical nonequilibrium dynamic states are induced by kinetic, rather than thermodynamic factors, and their existence offers a kinetic perspective on the origin and nature of living systems.

Overview

Seeking a physicochemical characterization of the simplest living entity has long challenged the physical sciences. How can a simple living system be understood in physicochemical terms? How could such a system have emerged, and how can its unique biological characteristics, seemingly in defiance of conventional physical law, be explained? The recent discovery of the existence of a previously unknown kinetic dimension within chemical space (Boekhoven et al. 2015) has reaffirmed the existence of a stability kind in chemistry, dynamic kinetic stability, one applicable to energy-fuelled dynamic chemical systems (Pross and Khodorkovsky 2004; Pascal et al. 2013; Pross and Pascal 2013; Pross 2016, 2019; Pascal and Pross 2019). That stability kind allows the characterization of living systems in kinetic rather than thermodynamic terms, thereby offering new insights into the physical basis for life. Building on that kinetic base, together with established kinetic principles (Szathmáry and Gladkih 1989; Lifson 1997), suggests that a chemical replicative system, once activated into the DKS state, would be expected to evolve irreversibly toward increasing DKS (Pascal and Pross 2015; Danger et al. 2020). Accordingly, a strategy for the synthesis of dynamic nonequilibrium replicative systems, able to evolve and complexify – a model for simple protolife – now appears feasible (Pascal and Pross 2017; Yang et al. 2021). The existence of a kinetic dimension in chemical space, resting on the concept of dynamic kinetic stability, may help narrow the conceptual gap that has long divided the physical and biological sciences.

Dynamical Friction

Sean N. Raymond
Laboratoire d'Astrophysique de Bordeaux,
CNRS, Université de Bordeaux, Bordeaux,
France

Definition

Dynamical friction is a force exerted by small objects that damps the random motions of large objects. This occurs via a gravitational “focusing” of small bodies behind the orbit of the large body. This is different than viscous stirring, which is simply an equipartition of energy between large

and small bodies. In the context of planet formation, dynamical friction from planetesimals acting on ► [planetary embryos](#) keeps the eccentricities and inclinations of the embryos relatively small such that collisions between embryos only occur once the planetesimal population is largely depleted.

Dynamical Instability

Rory Barnes
Astronomy Department, University of
Washington, Seattle, WA, USA

Definition

A dynamical instability is a nonlinear response to a phenomenon that ultimately leads to a large-scale change in a system. This term may be applied to any type of dynamical system, such as orbits, atmospheres, interiors, etc. For example, during planet formation, the dust layer of a ► [protoplanetary disk](#) is compressed, increasing the density and ultimately coalescing the dust into ► [planetesimals](#). On a large scale, if the gas layer becomes cold enough and is massive enough, the gas can collapse into a ► [giant planet](#). After planet formation if two planets come close to each other, their orbits can be dramatically altered, perhaps even resulting in one being ejected from the system. In these examples, the particles (dust, gas, or planet) had been orbiting the star in the same way for a long time, but the orbit, or the particle itself,

was quickly (usually in just a few to a few thousand orbits) changed.

Planetary magnetic field · Planetary magnetism

Synonyms

[Magnetic field generation](#)

Definition

A dynamo – generally – generates electric and magnetic energy from kinetic energy through the physical process of electromagnetic induction. A current will be induced in a closed wire moving through a magnetic field. The current by itself will generate a magnetic field. In planetary interiors, a similar although more involved mechanism can produce a global ► [magnetic field](#); convective flow of an electrically conducting material in a magnetic field will induce a current that will generate a magnetic field. If certain conditions are met, the magnetic field will maintain or amplify the original magnetic field.

Overview

Generation of a magnetic field requires an electrically conducting shell within a ► [planet](#), motion within that shell, and a “seed” magnetic field. For recent reviews on dynamo problems, see Busse

and Simitiev (2015), Christensen and Wicht (2015), and Roberts (2015). In the ► [terrestrial planets](#) and the satellites, this region is agreed to be the fluid iron-rich core at the center. In the ► [Giant Planets](#) ► [Jupiter](#) and ► [Saturn](#), the dynamo region is agreed to be the metallic ► [hydrogen](#) shell and in ► [Uranus](#) and ► [Neptune](#) a comparatively shallow layer of ionized fluid (see, e.g., Connerney 2015 for a review). In the terrestrial planets and satellites, there may be a solid inner core, the growth of which would provide a buoyancy flux that may drive the dynamo. This buoyancy then derives from a difference in composition between the solid inner core and the fluid outer core. Light alloying elements such as sulfur and oxygen tend to be expelled from the solidifying core and to form a buoyant layer above the inner core that tends to rise and mix with the outer core. In addition to (or instead of) a chemical buoyancy flux from the inner core, thermal buoyancy may drive the flow. The thermal buoyancy would result from a sufficiently large temperature difference between the core and the silicate rock ► [mantle](#) surrounding the core. Fluid cooled at the core-mantle boundary will tend to sink toward the center and thereby drive the convective flow. Thus, an entirely liquid core can support a thermal dynamo. There is a difference in efficiency between the thermal dynamo and the compositionally driven dynamo. While the thermal dynamo as a heat engine is subject to a Carnot efficiency (about 0.05, Gubbins et al. 2003), a compositionally driven dynamo is not as restricted. In the giant planets, thermal buoyancy is usually thought to drive the flow although helium droplets falling out of solution with hydrogen may provide a buoyancy flux (see Guillot and Gautier 2015 for a review). It should be mentioned that precession and tides have also been suggested to excite flow instabilities in the core and a dynamo (e.g., Tilgner 2015 for a review).

Convection in the dynamo region can be described by the field equations of fluid dynamics (e.g., Busse and Simitiev 2015). Because of the magnetic field, the electric currents, and the planetary rotation, the Lorentz and Coriolis force have to be included. The momentum equation then is

$$\rho \left(\frac{\partial}{\partial t} + \mathbf{v} \cdot \nabla \right) \mathbf{v} + 2\rho \mathbf{\Omega} \times \mathbf{v} = \nabla p + \rho \mathbf{g} + \mathbf{j} \times \mathbf{B} + \rho \mathbf{F}. \quad (1)$$

In Eq. 1, t denotes time, $\mathbf{v}$ is the fluid velocity, ρ is density, $\mathbf{\Omega}$ is the planet's rotational angular velocity vector, p is pressure, $\mathbf{g}$ is gravity, $\mathbf{j}$ is the electric current density, $\mathbf{B}$ is the magnetic induction vector, and $\mathbf{F}$ is the specific body force (buoyancy). Vector quantities are written in bold face. The first term on the left-hand side is the inertia term, and the second term denotes the Coriolis force. The first two terms on the right-hand side denote pressure variations and the hydrostatic pressure. The third term is the Lorentz force, where $\mu \mathbf{j} = \nabla \times \mathbf{B}$ with μ the magnetic permeability. The equation is supplemented by conservation of mass and entropy equations and by an equation of state.

The magnetic induction equation (written in a simplified form assuming a solenoidal velocity field and a constant magnetic diffusivity λ) is

$$\frac{\partial \mathbf{B}}{\partial t} = \nabla \times (\mathbf{v} \times \mathbf{B}) + \lambda \nabla^2 \mathbf{B}. \quad (2)$$

A sustained magnetic field can be generated by the flow if the production of field energy by shearing the field (first term on the right-hand side) overcomes the magnetic diffusion (second term on the right-hand side). The first term also shows that certain restrictions apply to the flow. A flow directed along the field lines, for instance, will not contribute to the dynamo. The relative weight of the two terms is measured by the magnetic Reynolds number

$$\text{Re} \equiv \frac{Ud}{\lambda}, \quad (3)$$

where U is a characteristic velocity and d a characteristic length (e.g., the core radius). The magnetic Reynolds number must be larger than 1 for the dynamo to operate. Other dimensionless parameter groups of relevance to the dynamo problem are the Rayleigh number that measures the vigor of the convection and the Ekman

number that measures the importance of the Coriolis force.

Numerical models of the dynamo driven by a buoyancy flux from below (a growing inner core) have been successful, but the models are still far from realistic values of both the Ekman and Rayleigh numbers. Nevertheless, a scaling law has been derived for the magnetic field strength at the surface of a core dynamo region (Christensen and Aubert 2006):

$$B \approx 0.9 \mu^{\frac{1}{2}} \rho^{\frac{1}{6}} \left(\frac{g Q_B d}{4\pi R_c R_i} \right)^{\frac{1}{3}}, \quad (4)$$

where Q_B is the buoyancy flux into the dynamo region (thermal and/or chemical) and R_c and R_i are the outer and inner radii of the core shell. The characteristic length d here is the thickness of the fluid core shell $R_c - R_i$. In this scaling, the magnetic field strength depends on the size of the core and the buoyancy flux but is independent of the electrical conductivity and of the rotation rate, although it is still required that the magnetic Reynolds number be larger than 1 and that in order to obtain a dipolar field, the Coriolis force must dominate over inertia. (The latter requirement is consistent with Cowling's theorem; see Roberts 2015.) The scaling is similar in conception to a scaling introduced by Stevenson et al. (1983), although the exponents in the power law differ. It is important to note that this scaling supersedes an older scaling law that was derived from a balance between the Lorentz force and the Coriolis force terms in Eq. 1. In the latter scaling – often used in the astrobiology literature when discussing the habitability of exoplanets – the magnetic field was considered proportional to the planetary rotation rate (see Hubbard and McFarlane 1980).

As Eq. 4 shows, the magnetic field strength depends on the rate of heat transfer through the mantle of a terrestrial planet or satellite. The buoyancy flux is directly related to the ► [heat flow](#) extracted by the planetary mantle from the core for a thermally driven dynamo. For a chemically driven dynamo, the rate of inner core growth and

therefore the rate of buoyancy release depend on the core cooling rate and therefore – again – on the heat flow from the core. The heat flow from the core can be calculated from thermal history models. This underlines an important property of terrestrial planets: A terrestrial planet may or may not have a magnetic field, and the existence of a field is not easily predicted from observations of bulk planetary parameters.

Definition

The European Astrobiology Network Association (EANA) was organized in Spring 2001 during the First European Workshop on Astrobiology co-organized with ► [ESA](#) at the ESRIN research facility in Frascati, Italy. Acknowledging that there are numerous centers of excellence in astrobiology in Europe, founders decided to promote their work by setting up this European Network to help the sharing of their expertise

and facilities. This network aims also to attract young scientists to participate practically in this evolving interdisciplinary field. Other goals are the promotion of astrobiology to European funding agencies (ESA, ESF) and political bodies such as the European Commission. Finally, individual members as national associations are invited to promote a public interest in astrobiology.

Up to 2010, scientists or organizations of 19 European countries are participating in this network: Austria, Belgium, Czech Republic, Denmark, Finland, France, Germany, Greece, Hungary, Italy, Portugal, Spain, Sweden, Switzerland, The Netherlands, Poland, Romania, Russia, and the UK. EANA holds annual workshops alternately in the different member countries.

EANA was established as an affiliate partner of the NASA Astrobiology Institute in early 2002. EANA is also associated with the Commission of Astrobiology, Space Life Origin and Evolution at the Chinese Society of Space Research, and the Japanese Astrobiology Network.

Earth

Daniele L. Pinti

GEOTOP Research Center for the Dynamics of the Earth system, Université du Québec à Montréal, Montréal, QC, Canada

Definition

The Earth is the planet on which we live. It is the third planet from the Sun and one of the four telluric (or rocky) planets situated in the inner part of our ► [Solar system](#). It is a differentiated planetary body, which means that the elements composing the planet were redistributed based on their physical or chemical behavior (e.g., density and chemical affinities). The Earth is differentiated into the Fe-Ni metallic core, two silicate shells, the ► [mantle](#) and the ► [crust](#), the ocean, and the atmosphere. The crust is further differentiated in ► [oceanic crust](#), made essentially of ► [basalt](#), ► [gabbro](#), and ► [peridotite](#), and a ► [continental crust](#) essentially made of not only more felsic Al-rich silicate rocks such as igneous andesites and granites, but also sediments and metamorphic rocks. It is distinguished from other rocky planets of our Solar system by the near absence of old cratered surfaces – wiped off by more than 4 Gyrs of tectonic and ► [weathering](#) processes, by the presence of oceans and of a thick atmosphere. Earth is so far the only planet in the Universe where life is demonstrably present.

Overview

The Earth is the only easily accessible natural laboratory for astrobiologists to study planetary conditions which can favor the initiation of life. ► [Titan](#), the Saturn's moon, is considered the Earth at its prebiotic stage, i.e., when inorganic or organic chemical reactions took place producing some sort of ► [primordial soup](#) in a natural environment before the advent of life. Therefore, the geological conditions prevailing

at the surface and inside the Earth since its beginning are important in order to assess plausible scenarios of environmental conditions where life could have flourished. Here below, a very first-order and raw overview of the early evolution of Earth is reported. Specific entries of the Encyclopedia (several here suggested) are necessary to be read for having a larger vision of the several concepts here briefly introduced.

Earth has a mean radius of 6371 km and a mean density of 5.513 g cm^{-3} , the latter comparable to that of planet ► [Mercury](#) (5.43 g cm^{-3}). It is the largest of the rocky planets of the Solar system, with ► [Venus](#) slightly smaller (radius of 6052 km). Its distance from the Sun is around 149 million kilometers which corresponds to 1 ► [AU](#) (astronomical unit), for convenience. The Earth accreted in the inner Solar system, somewhere between the present-day orbits of Mercury and Venus and a few tenths of million years after the formation of the Solar system (e.g., Canup 2008; Yu and Jacobsen 2011), estimated at 4.57 Ga ago (e.g., Bouvier and Wadhwa 2010; Connelly et al. 2017). The Earth is differentiated, i.e., elements composing the accreted planet were redistributed according to their densities (gravitational differentiation: heavier metal down in the core, lighter silicates up in external shells, and volatiles outside) and chemical affinities (chemical differentiation). Planetary differentiation was triggered by melting caused by latent heat of accretion, heat from decay of long-lived and short-lived ► [\(extinct\) radionuclides](#). The timing of this differentiation is still a matter of debate, and mainly based on measurements of short-lived isotopic systems such as $^{144}\text{Nd}/^{142}\text{Nd}$ (Boyet and Carlson 2005) or $^{182}\text{Hf}-^{182}\text{W}$ (Kleine et al. 2009), which suggest differentiation took place somewhere between 30 and 200 Ma after the accretion of the Earth (Nimmo and Kleine 2015). The first protocrust of the Earth was likely mafic in nature and basaltic in lithological composition. More felsic continental crust developed at a later stage by remelting the felsic crust (*anatexis*) and production of granitoids. This process took a long time, and models suggest that continental crust had

reached a volume similar to its modern value by 3.0 Ga ago. Present-day composition (andesitic-granitic) of the continental crust could have been reached even later. The advent of plate tectonics, as we know it today, is not well dated. It may have appeared early and possibly operated with slightly different mechanisms. Some authors suggest, however, that it was not at work before 3.0 Ga ago or even later. This process is very important because it regulates any exchange of energy, heat, elements, and potential nutrients from the hot interior of the Earth to the surface and back to the mantle, and likely played a key role in favorizing development of life (e.g., Hall 2017). Primitive secondary atmosphere of the Earth, brought by asteroidal and cometary impacts, was likely composed dominantly by the CO₂ (>95% v/v) and N₂ (<5% v/v), as are the present-day residual primitive atmospheres of Venus and Mars (e.g., Pinti 2021). It is possible that other greenhouse gases such as CH₄ were present which compensated the weak luminosity of the Sun (► **Faint Young Sun Paradox**) and maintained the surface of the Earth above freezing (Pavlov et al. 2000). This atmosphere evolved toward an N₂-O₂-dominated atmosphere through eons, by progressively locking CO₂ into carbonates (CO₂ geological sequestration) and adding O₂ by a complex interplay of increasing sources (bacteria respiration) and reduction of sinks (reduced to oxidizing volcanic gases; organic matter preservation in sediments) (Catling 2015).

It is generally held that the planet Earth initially was an inhabitable inferno too hot for any kind of organism, including extremophiles, to survive. More clement climatic condition at the surface of the Earth (► **Cool Early Earth**) was nevertheless established within a few hundred million years. This was clearly established by oxygen isotopes in some of the Jack Hills zircons (Australia), a ubiquitous minor mineral of granites. Some of these zircons older than 4.1 Ga show excess ¹⁸O relative to mantle-derived rocks, which indicates that the source of their parent granites included low-temperature sediments and therefore that liquid water was undoubtedly present at the surface of the Earth.

History

If the scientific investigation of the atmosphere really started in the seventeenth century, the problem of its origin was taken into account only two centuries later. It is indeed with the works of Galileo Galilei, Blaise Pascal, and Robert Boyle that the notion of pressure and temperature permitted to study in a quantitative way the atmosphere. John Mayow, Boyle's student, concluded, in an empirical way, that the air is a two-body mixture out of which one takes place at once in breathing and burning. In 1777, Antoine-Laurent de Lavoisier initiated an analysis and synthesis of air, and found out the "aerial nitrogen" and "oxygen" terms to name the two gases of the atmosphere. In his memoir "*Vues générales sur la formation et la constitution de l'atmosphère*," Lavoisier even thought of the possibility of the existence, at a high altitude, of a hydrogen film, which would sometimes be destroyed completely by combustion and would form again by the continual decomposition of plant and animal matters generated at the earth's surface.

In 1833, the French physicist André-Marie Ampère drew the conclusions from Laplace's hypothesis concerning the solar system origin and, taking up the Lavoisier's point of view and expressing the idea that the earth's atmosphere results from a reduction of bodies oxygenated by metals, leading to a nitrogen release originally combined to oxygen, explaining also the origin of oxygen in the atmosphere. As far back as 1856,

the Belgian chemist Cornille Jean Koene considered a link between oxygen and carbonic acid gas, inferring the lack of oxygen gas in the original terrestrial atmosphere because of a reducing medium due to the occurrence of metal or sulphide compounds. Finally, in the 1920s, the Russian Wladimir Vernadsky introduced, by his biosphere concept, the idea of a balance between atmosphere and human beings: for him, gases of the atmosphere are in an equilibrium state of dynamic and perpetual exchange with living matter.

It is only in 1951 that American geologist William Rubey in a seminal paper (Geologic history of sea water: An attempt to state the problem) that a modern theory of the origin of the atmosphere shaped up. Rubey proposed that the Earth's atmosphere did not originate from the weathering of the continental crust, a view that was popular among geologists at that time, but rather originated from volcanic degassing throughout geological times. The development of the noble gas geochemistry in that period supported this view. Von Weizsäcker (1937) clearly understood that the gaseous argon-40 was a product of degassing of the solid potassium-40 which resides in the crustal rocks. Analyses of radiogenic nuclides of neon, argon, and xenon in the 1980s (Allègre et al. 1986/1987) allowed quantifying a chronology of the degassing and demonstrated that majority of atmospheric gases did not derived from primordial gases from a primitive solar nebula but rather added shortly later the formation of the Earth by meteoritic and/or cometary material (Dauphas 2003).

volatiles · Meteorites · Nitrogen · Noble gases ·
Water

Definition

The Earth's atmosphere is a thin gaseous layer made of oxygen, ► **nitrogen**, and trace gases. It permits a mild temperature and provides a protection against cosmic rays, solar wind, and meteorite falls. It was stable enough through geological time to have nurtured the development of life.

Originally, the atmosphere consisted of water, carbon dioxide, nitrogen, sulfur, and ► **noble gases**, and it evolved by condensation of water to form the oceans, trapping of ► **carbon** in carbonates and organic matter, and biogenic production of oxygen. The Earth's atmosphere originated probably from the addition of bodies from the asteroid belt between Mars and Jupiter toward the end of terrestrial formation.

Overview

The Earth's atmosphere consists mainly of oxygen (20.95% O₂) and nitrogen (78.078% N₂), the other constituents making only 1% of the total volume: argon (0.934%), CO₂ (preindustrial: 280 ppm vol/vol), and noble gases. This composition is unique among planetary atmospheres: atmospheres of the giant planets (Jupiter, Saturn, Uranus, Neptune) are dominated by hydrogen and helium, reflecting the composition of the protosolar nebula, whereas the atmospheres of the inner planets, Venus and Mars (Mercury does not possess an atmosphere), are rich in CO₂, the concentration of N₂ being of the order of a few %. The high oxygen content of the terrestrial atmosphere is a byproduct of the development of life. Oxygen is produced by photosynthesis, a mechanism that uses solar photons to break down and oxidize organic molecules. Without life, oxygen would disappear in a few thousand years due to iron oxidation in terrestrial rocks. The very low CO₂ content of air is the result of trapping of carbon in rocks, either as carbonates or as organic matter buried in the crust. If carbonates were dissociated to release CO₂, the resulting atmospheric pressure would be around 27 bars, and the CO₂/N₂ ratio would be comparable to those of Venus and Mars atmospheres. Oceanic water, which is liquid under the Earth's surface conditions but was probably gaseous during the formation of the Earth, was part of the early atmosphere. If oceanic water was vaporized and oceanic halogens (components of salt) transformed into their gaseous forms (HCl, HF, HBr), then the atmospheric pressure would be 220 bar instead of 1.01 bar, and the Earth's surface would be an

inferno hostile to life. The reason why Earth escaped such hellish fate (while Venus kept CO₂-rich atmosphere with a pressure of 90 bar and a surface temperature of 450 °C) is unclear and is the focus of active research.

Origin of the Terrestrial Atmosphere

The “reconstructed” atmosphere’s composition, that is, the sum of volatile elements in the air, in the oceans, and in sedimentary rocks, consists of 86% water vapor, 12% CO₂, 1.4% HCl + HF, and 0.2% N₂. This composition is quite comparable to that of volcanic gases emitted by active volcanoes. This observation led Williams W. Rubey, a geologist at the US Geological Survey, to propose that the Earth’s atmosphere did not originate from weathering (chemical alteration) of the continental crust, a view that was popular among geologists at that time, but rather originated from volcano degassing throughout geological times (Rubey 1951). In support of this view was the discovery of the decay of ⁴⁰K (a rare isotope of potassium) producing ⁴⁰Ar, the most abundant isotope of the noble gas argon. In fact, the 0.934% abundance of Ar in the air is almost entirely due to ⁴⁰Ar, the other more abundant argon isotope, ³⁶Ar, having an atmospheric concentration of only 32 ppm vol. The discoverer of the ⁴⁰K decay, Von Weizsäcker, a German physicist in pre-World War II Germany, noted correctly that the high ⁴⁰Ar content of air was the result of the ► [degassing](#) of the “solid,” silicate-rich Earth, where potassium resides (Von Weizäcker 1937). This key observation led to the concept of atmospheric formation by degassing of volatile elements trapped in the mantle. This concept was refined using noble gases. Some of the isotopes of the chemically inert elements, now in the atmosphere, were produced by natural nuclear reactions like radioactive decay and spontaneous fission of parent elements contained in the mantle and crust, thus establishing a chronology of atmospheric formation. The terrestrial mantle also contains volatile elements including noble gases. A comparison of noble gas isotopic compositions between the mantle (which can be sampled in

basalts originating from mantle melting) and the atmosphere shows that the latter formed very early in the Earth’s history, within ~100 Ma after the start of solar system formation, 4.57 Ga ago (Ozima 1975; Staudacher and Allègre 1982).

There is evidence that a source other than mantle degassing contributed to atmospheric formation. On the one hand, models of ► [solar system](#) dynamics suggest that the Earth formed in a region of the nascent solar system that was too energetic to permit trapping of volatile elements into planetary embryos. Therefore, it has been proposed that terrestrial volatiles might have been contributed directly by impacting of bodies originating away from the present-day Earth radial location, in a region between Mars and Jupiter where volatile-rich meteorites, called the carbonaceous chondrites, originate. From dynamical reasons, these contributions might have happened toward the end of the terrestrial accretion once more than 90% of the Earth was formed (Morbidelli et al. 2000). On the other hand, the noble gas isotopic composition of ► [mantle volatiles](#) is significantly different from that of the atmosphere, which suggests either different cosmochemical sources for the mantle and the atmosphere (Marty 1989) or drastic atmospheric processing such as escape of volatiles to space that could have fractionated noble gas isotopes (Pepin 1991). In particular, the isotopic composition of mantle neon is close to that observed in the solar nebula (Sarda et al. 1988), which suggests that part of volatile elements originated from the nebular gas or from matter implanted by ions from the young Sun. This problem is not yet resolved, but some insight arises from the stable isotopes (i.e., the isotopes that are not produced or destroyed by nuclear reactions) of water and nitrogen. The ratios of the two hydrogen isotopes from the water molecule, D/H (where D stands for deuterium, or ²H, and H for ¹H), and of the two isotopes of atmospheric nitrogen, ¹⁵N/¹⁴N, are comparable to values found in primitive meteorites, also called chondrites (Marty 2012; Alexander et al. 2012). They are markedly different from the isotopic signatures of the cloud of gas and dust that collapsed to form the solar system and from isotopic ratios measured in comets

(another potential source of atmospheric volatiles, since comets, which come from the outer solar system beyond the orbit of Neptune, are very rich in volatile elements with water making up to 50%). Hence, major volatiles like water and nitrogen, and probably carbon too, seem to originate mostly from bodies within the inner solar system, akin of present-day asteroids between Mars and Jupiter. This scenario is consistent with dynamical models advocated above in which volatile-rich asteroidal bodies contributed to Earth toward the end of accretion. These bodies were not necessarily big, and gas-rich dust like interplanetary particles or micrometeorites could have played a significant role (Maurette et al. 2000). Mass balance considerations involving siderophile as well as lithophile elements indicate that the contribution in volatile-rich material at the end of accretion could have made only $\sim 0.3\%$ of the total terrestrial mass. However, the amount of terrestrial volatiles is equivalent to about 2% carbonaceous chondrites, which suggests that the supply of volatiles to the proto-Earth was a continuous process and was not restricted to the last stages of terrestrial accretion (Marty 2012). Recently, the in-situ analysis of noble gases in the coma of comet 67P/Churyumov-Gerasimenko by the ESA Rosetta mission established a genetic link between cometary volatiles and the terrestrial atmosphere, suggesting that about 20% atmospheric Xe and Kr could be cometary (Rubin et al. 2018).

Atmospheric noble gas isotopes indicate also that the early atmosphere had been escaping to space for prolonged periods of time of the order of several hundreds of million years, as a result of intense UV irradiation by the early Sun, which dissociated the water molecules (Hunten et al. 1987). Meanwhile, large bodies battered the Earth, resulting in large-scale melting and vaporization. Such high temperature episodes did not last for more than 1 or 2 Myr due to radiative heat loss into space, and, at some stage, the water vapor started to condensate to form the oceans. According to the isotopic record of some rare, very ancient, $\blacktriangleright$ [zircons](#), liquid water might have existed as soon as 4.37 Ga ago, that is, only ~ 150 Ma after the start of terrestrial accretion. Besides water, the Earth's surface needed to get

rid of CO_2 also: this species, the likely prevalent form of carbon in the early atmosphere, is a strong greenhouse gas that, if abundant, could have prevented cooling of the Earth's surface to the condensation temperature of water. How this took place is unclear: carbon might have been efficiently returned to the mantle by subduction (Zahnle 2006), or it could have formed carbonates, providing that liquid water was available and Ca^{2+} ions were removed by surface alteration of basalts.

It is probable that, before 3.8 Ga ago, large ocean volumes already existed, as indicated by the occurrence of sedimentary rocks in geological formations of this age. The carbon isotopic composition of graphitic inclusions, encapsulated in apatite in quartz from 3.86 Ga-old meta-sedimentary rocks from $\blacktriangleright$ [Akilia](#), West Greenland, suggests that life already existed (Mojzsis et al. 1996), but this record is still controversial. Around 3.8 Ga ago, a $\blacktriangleright$ [Late Heavy Bombardment](#) (LHB) of extraterrestrial material is recorded at the lunar surface by Maria craters dated at 3.85–3.85 Ga (Tera et al. 1974). Scaled to the Earth's dimensions, the LHB would have contributed an average thickness of about 200 m of extraterrestrial matter onto the whole Earth's surface. Modeling of solar system dynamics suggests that the LHB was due to a large-scale perturbation of the outer solar system and that both comets and asteroidal bodies were involved (Gomes et al. 2005). This episode had certainly significant impact on the atmospheric composition (and on the survival of living matter, if any), but such effect is presently unknown.

The composition of the early atmosphere is constrained by the rock record. The composition of ancient lavas called $\blacktriangleright$ [komatiites](#) indicates that their oxygen fugacity (a measure of the oxidation state of a mineral assemblage) was close to that of modern lavas (Canil 2002). The gas phase in equilibrium with such a molten magma contains water vapor, CO_2 , and N_2 as the main species of H, C, and N. Hence, the early atmosphere of the Earth in the Hadean (4.4–3.8 Ga) was probably oxidizing and not reducing as proposed from experiments aimed to produce amino acids in a reduced gas mixture upon electric discharges

(Miller 1953). How oxidizing the atmosphere was during the first 1–2 Ga is not clear yet. Sulfur in sedimentary rocks of the Archean eon (the geological eon between 3.8 Ga ago and 2.5 Ga ago) contains isotopic anomalies that are best explained by interactions between atmospheric species and ultraviolet irradiation of the Sun. At present and presumably since 2.4 Ga, most of solar UV irradiation is absorbed in the higher atmosphere by oxygen species, notably ozone. Hence, the evidence from sulfur isotopes that UV photons could penetrate deep in the atmosphere has been taken as evidence that free oxygen was not present in the atmosphere until 2.4 Ga ago (Farquhar et al. 2000).

During the first half of the Earth's history, the Sun was less luminous, and the energy reaching the terrestrial surface was ~25% smaller than the present-day one (Kasting 1993). However, no glaciation took place in the Archean eon (the so-called ► [faint young Sun paradox](#)), and there is evidence that the oceans were hotter, up to 70 °C on average, than the present-day oceans (Robert and Chaussidon 2006; ► [Precambrian Oceans, Temperature of](#)). More CO₂ in the Archean atmosphere might have helped in keeping the Earth's surface warm, but the required level is beyond what the sedimentary record from this time has preserved in terms of CO₂ partial pressure (e.g., Shaw 2008). The existence of methane in the Archean atmosphere requires a strong source, and the only significant one could be CH₄-producing bacteria. Alternatively, it has been proposed that more N₂ in the atmosphere would have helped to preserve a significant greenhouse effect in the Archean, by increasing Rayleigh backscattering (Goldblatt et al. 2009). However, the fossil record of the Archean atmospheric N₂ pressure is not consistent with a high partial pressure of N₂ in the Archean atmosphere (Som et al. 2012; Marty et al. 2013) and even suggests a much lower pressure than today. Hence the faint Sun paradox requires another type of explanation, which is still discussed. There is no consensus about the time of appearance of free oxygen in the atmosphere, a strong indication of colonization of the Earth's surface by living matter. Different lines of evidence point

to a (geologically) brutal increase of the partial pressure of O₂ around 2.35 Ga ago, the Great Oxygenation Event when life-related sources of oxygen took over oxygen consumption by basalts (Holland 2002), and the isotopic signature of sulfur in sedimentary rocks discussed above seems to support this view.

Future Directions

There is no doubt that significant advances in our understanding of the origin and evolution of the atmosphere will arise in the near future. First, several planetary missions are documenting potential extraterrestrial sources of volatile elements to terrestrial planets. The NASA Genesis mission has sampled solar wind ions for 27 months with the aim to analyze the isotopic composition of the Sun. The ► [Stardust mission](#) has sampled cometary grains, and one of the objectives of the mission is to investigate possible links between cometary matter and volatile elements of the terrestrial planets, and missions are on the way or under development to sample and analyze in situ comets and asteroids. The analysis of other planetary atmospheres has allowed better insight in the origin of atmospheres of giant and inner planets. The in-situ analysis of the Martian atmosphere has allowed exceptional insight into the evolution of the atmosphere of the red planet (Conrad et al. 2016), and several missions are now targeting the composition of Venus and its atmosphere. In parallel, the analysis of ancient sedimentary rocks with low metamorphic grade will help to better constrain the composition and thermal state of the atmosphere and oceans in the past, and several drilling projects in ancient terranes ► [Archean drilling projects](#) are sampling unaltered rocks for this purpose.

Definition

The age at which material condensed from the ► [Solar Nebula](#) ceased to significantly add to the Earth.

History

Around 1850, British physicist Lord Kelvin (William Thomson) elaborated on the theory of heat conduction formulated by the French physicist and mathematician Joseph Fourier and concluded that the Earth was no more than a few tens of Ma old. Kelvin also fiercely opposed the geologists who guessed from modern sedimentation rates that the Earth was older than a billion years. However, by World War II, the general agreement among scientists was that the Earth was older than 3 billion years. It is often incorrectly stated that Kelvin's mistake, one of the most devastating in the history of modern physics, was due to his ignorance of radioactive heating. It was British geologist Arthur Holmes who pointed out that the loss of heat from the interior of the Earth is largely controlled by mantle convection. In 1954, American geochemist Clair Patterson brought the controversy to an end by showing that meteorites and the Solar System are some 4.55 Ga old and that the age of the Earth cannot be very different.

Overview

Even though the age of our planet is occasionally presented as controversial, mostly on religious grounds, all scientists agree that it started forming some 4567 million years ago. Two real issues cloud the discussion. First, there is no original rock sample of that age left on our planet: the oldest crustal segment is 3.8 Ga old (Isua Supracrustal Belt, West Greenland), the oldest rock is some 4.1 Ga old (Acasta gneiss, Canada), while the oldest undisputable mineral ages are 4.3 Ga old detrital zircons (Jack Hills, Western Australia). The problem of the age of the Earth is therefore best addressed by dating the earliest objects of the Solar System, the calcium-aluminum-rich refractory inclusions (► [CAIs](#)) found in some chondritic meteorites and applying a comparative chronology based on extinct radionuclides to both terrestrial samples and meteorites in order to date the Earth's formation. The U-Pb age of CAIs is rather well established at 4568.0 ± 0.5 Ma. The small glass blebs found in

chondrites, which are known as ► [chondrules](#), are 1–3 Ma younger than the CAIs. The ► [radioactivity](#) of the extinct ^{182}Hf nuclide ($T_{1/2} = 8.5$ Ma) requires that the terrestrial core segregated 30 Ma after the formation of CAIs, which places a strong constraint on the age of the planet itself. Similar, but less tight constraints are placed by other extinct nuclides (^{129}I , ^{244}Pu) and by ^{235}U . The early Solar System evolved by condensation of the nebular gas followed by dust agglomeration and then by coalescence of asteroid-sized bodies and their merging into a few tens of protoplanets. A second issue therefore is a matter of definition: how long did the accretion stage last? Astronomical evidence indicates that UV and X-rays emitted by proto-(T-Tauri)-stars similar to the Sun had blown off the nebular gas and that the disk of debris was swept clean in less than 5 Ma. Dynamic models suggest that the period during which protoplanets merged to form planets as we know them today may have lasted for a few extra tens of Ma.

Definition

Earth formed as a silicate- and metal-rich body in the same context of the other inner Solar System “terrestrial” worlds. In its early evolution, it separated into layers (core, ► [mantle](#), ► [crust](#)) because of the chemical and mechanical properties of the materials that accreted to the Earth. The surface zone stabilized within the first 100 million years of Earth's existence and has hosted geochemical cycles modulated in whole or in part by the presence of liquid water and an atmosphere since about 4.4 Ga ago.

Overview

Introduction

Earth is a natural and accessible planetary-scale laboratory to test ideas to be used in the search for life elsewhere in the solar system and beyond. An understanding of Earth's origin is essential to the discipline of astrobiology, at least for the reason that this planet is the singular known repository of Life. Studies of the origin and early evolution of Earth have undergone dramatic shifts in recent years and have radically changed our knowledge of its formative time and how early events led to a habitable planet. This knowledge logically forms the basis of ongoing searches for other habitable solar system's exoplanets in the galactic neighborhood. More than 4000 planets around other stars have been documented by various methods, mostly within a sphere of space around $3 \times 10^9 \text{ ly}^3$ (ly = light years). Yet it remains to be seen whether the specific orbital architecture of our solar system that includes habitable rocky ► [“terrestrial planets”](#) with liquid water within a few

astronomical units of a G-type star is exceptional or commonplace.

Early Earth was a vastly different planet from the one we are so familiar with today. The surface was heated from below by radioactivity, thermal conduction through the ► [crust](#), and vigorous small-scale convection cells of ► [magma](#) and mainly from above by the muted radiation of a faint young Sun and by occasional meteoritic impacts. At first glance, it should have been uninhabitable. However, if there were liquid water, organic chemicals, and energy – all of which were present on this primeval surface – it is not unreasonable to suppose that the primordial chilled crust was the first platform in which processes of prebiotic chemistry, leading to the emergence of life (► [origin of life](#)) could have taken hold. Whatever the composition of the first crust was, the surface zone remained under a super-greenhouse atmosphere that kept temperatures within the stability field of liquid water.

The early terrestrial hydrous surface was continuously reworked by volcanic eruptions and meteoritic impacts that mitigated its long-term survival, which may be the reason why the oldest surviving terrestrial rocks or minerals date from 150 Myr after accretion (Harrison 2009). The long residence times of the oldest rocks in the crust means that almost any geological process could have been experienced by them. Over the intervening several billion years, ► [weathering](#), denudation, erosion, ► [metamorphism](#) (thermal, chemical, pressure induced, or all of the above), plate tectonics' subduction, remelting, reworking, and other crustal recycling processes had been at work to consume all but a minute fraction of what once existed from the first billion years of geologic time. Investigations focused on the origin of the hydrosphere and on when the crust evolved into the current basaltic (oceanic) and granitic (continental) dichotomy rely almost completely on information gleaned from a few outcrops or isolated minerals within much younger rocks from the oldest surviving terranes (Blichert-Toft and Albarède 2008).

That by 4.0 Ga the basaltic and the granitic crust was established on Earth and oceans as well as a rock cycle and the generation of

sediments is directly supported by the existence of metamorphosed remnants of granitoid rocks and isotopic systems. Yet older evidence from the geochemistry of detrital zircons (Jack Hills) tracks back to 4.4 Ga and shows that oceans and plate boundary processes (possibly plate tectonics?) could also have been present in the Hadean (Hopkins et al. 2008). Hence, the old prevailing view of a largely molten surface blasted by sterilizing impactors and intrinsically incapable of hosting life until after 3.8 Ga has been superseded by new data. The new view of the Hadean eon (4.567–4 Ga; see ► [Cool Early Earth](#)) and subsequent Eoarchean (4.0–3.6 Ga) favors by far an earlier origin of life than had previously been thought (Fig. 1).

Early Solar System, Earth, and Moon

The age of the solar system is calculated to be about 4.568 Ga (Connelly et al. 2008; Bouvier and Wadhwa 2010) based on geochronological studies of (CAIs = Calcium-Aluminum-rich Inclusions). CAIs are the earliest solids that are native to the solar system, which crystallized in the solar nebula before their eventual incorporation into meteorites. The paradigm for solar system formation begins with the collapse of part of a giant molecular cloud that itself formed from gas and dust expelled in the explosion of one or more massive stars. While the exact mechanisms responsible for the initiation of nebular collapse are unclear, nearby supernova explosions played a role in the initial gravitational/mass instabilities of the cloud based on the presence of the daughter products of some extinct short-lived nuclides in the oldest solids. Direct astronomical observations of giant molecular clouds containing young stars show that disk collapse and probable incipient dust grain formation around such stars is commonplace. In the planet-forming process, these grains aggregated into larger objects and eventually to planetesimals that were the building blocks of the planets.

A detailed chronology of the earliest events in the solar system, which span the time from the first solids through the origin of the planets and ultimately to the formation of the ► [crust](#), ► [hydrosphere](#), and biosphere, will long be an area of intense study. The physics of Earth

accretion has been explored in detail with sophisticated dynamical computational tools that model the interactions of planetesimals that led to the growth (and in some cases the destruction) of ever-larger bodies. Numerical simulations of terrestrial planetary growth succeed in modeling the formation of planets of the size and distribution as Mercury, Venus, Earth, and Mars. Such models show that most of the mass of the Earth accreted in 10 Myr but that there is an accretionary tail, which extends for an additional 100 Myr. Most of these dynamical models seem to indicate that the colliding planetesimals that built the terrestrial planets came from beyond Mars' orbit, or well beyond 2 AU (astronomical unit), and delivered volatile elements and compounds to the intrinsically dry, hot, inner solar system well inboard from the solar system's "frost line" close to the asteroid belt. The climaxing event in the Earth's formation and earliest evolution is the origin of the Moon, which was the result of the last big impact to affect the Earth.

The current paradigm favors the origin of the Moon no earlier than about 30 Myr into the history of the Solar System (i.e., from what is termed "t-zero" at 4.568 Ga). Model studies indicate that the Moon originated from a massive collision of the proto-Earth when our planet was about 90% of its present mass ($\sim 5.4 \times 10^{24}$ kg) with another planet of about Mars' mass (6.5×10^{23} kg). Earth's current mass is 5.974×10^{24} kg and that of the Moon is 7.35×10^{22} kg, so that it appears, that mass loss from the impact process was negligible. The impact was so energetic and deeply destructive that it yielded a dense, hot, CO₂-rock vapor-steam atmosphere of hundreds of bars on top of a vigorously convective magma ocean that occupied most of the Earth's interior. An orbiting ring of super-hot devolatilized rock vapor coalesced into the Moon (Canup and Asphaug 2001). The Moon-forming impact raised the whole Earth's temperature to that of a small red star (>2300 K) for several 1000 years. For the neo-formed Earth, most cooling models indicate that the hydrosphere recondensed out of the atmosphere in less than 10 Myr (Sleep et al. 2001). It has been suggested that oceans were present on the proto-Earth prior to the Moon-forming event (Abe 1993). If there was a primary hydrosphere, it

Earth, Formation, and Early Evolution, Fig. 1 Timeline of significant events in Earth's early formation and evolution

was wholly vaporized by the ► [giant impact](#). Consequently, it did not restabilize into a "secondary hydrosphere" until later when the surface cooled

to the point where liquid water could begin to pool on a dense primordial "chilled crust" of likely ultramafic (Fe- and Mg-rich) composition at the

top of the magma ocean (Arndt and Chauvel 1991). It is possible that a primordial crust and watery veneer of the postimpact Earth existed as early as about 35 million years after t_0 or around 4.53 Ga. A record of this primordial crust may never be found since all traces of it are expected to have been destroyed (cf. Carlson and Boyet 2009).

Not until 150 Myr after the foundation of the solar system (t_0) do we have direct evidence of the first (granitoid) crust from ancient terrestrial zircons (at 4.38 Ga), and only 500 Myr after that do we have the first direct evidence of surface conditions from marine sediments and basaltic lavas (ca. 3.83 Ga). Hence, the geologic record from actual rocks (as opposed to detrital zircons) only extends back from the present through $\sim 88\%$ of Earth history. The Hadean zircons bring this record up to a remarkable 95%. It is not impossible that older actual rocks will be found, but at present, the most ancient units are about 4 Ga old and found in the ► **Acasta Gneiss** Complex of northern Canada (Bowring and Williams 1999; Reimink et al. 2018). A gallery of ages for the next oldest rocks begins at the 3.77–3.87 Ga Isua Supracrustal Belt and the ► **Akilia** association (Nutman et al. 1996) in southern West Greenland and in Canada at the ca. 3.75 Ga Nuvvuagittuq Supracrustal Belt in northern Quebec (Cates and Mojzsis 2009). All of these outcrops are dominated by highly deformed ► **tonalite-trondhjemite-granodiorite** (TTG) gneisses that often (but not always) host supracrustal enclaves of amphibolites and other lithologies. Amphibolites in these cases are the metamorphic equivalents of volcanic and intrusive igneous rocks such as basalt, gabbros, and komatiites, and they sometimes host rare metamorphosed sedimentary rocks such as ferruginous siliceous schists (banded iron formations, BIFs). Pillow lavas in the Isua belt unambiguously attest to the presence of subaqueously erupted basalts.

Early Atmosphere

The Sun has increased its luminosity with time as its core increased its density by hydrogen fusing to helium. Standard models for the behavior of stars

in the main sequence predict that the Sun was only about 70% as bright in the visible part of the electromagnetic spectrum as it is now when it entered the main sequence 100 Myr after t_0 , around 4.46 Ga (Ribas et al. 2005). The Sun had only brightened slightly more to $\sim 77\%$ present value by the time of the earliest morphological evidence of life in the form of bio-sedimentary structures (stromatolites) and purported microbial microfossils which appear much later in the rock record, about 3.5 Ga ago in the Dresser Formation in Western Australia (Van Kranendonk 2006). A dimmer early Sun remains a long-standing and mostly unresolved problem for atmospheric models that seek to keep the early Earth warm enough for liquid water to remain stable. So far, it is very difficult for these models to account for a warm early Earth, and no atmospheric models succeed in keeping ancient Mars above 0 °C. In the absence of abundant and efficient greenhouse gases, such as water vapor, CO₂, CH₄, and NH₃, the Earth before about two billion years ago ought to have been ice covered to equatorial latitudes (Snowball Earth, Hoffman and Schrag 2002). The only credible solution to account for oceans of liquid water is to have a denser atmosphere rich in powerful greenhouse gases compared to anything that has existed in the Phanerozoic time. Relatively speaking, there has been but a small variation in greenhouse gases – well within several tens of percent of present atmospheric concentrations – over the last 500 Myr.

Broad estimates for average surface temperature of the early Earth depend strongly on what plausible limits can be placed on CO₂, CH₄, and NH₃ abundances and the sources and lifetimes of these gases in the atmosphere. If all carbon currently present in Earth's crust as carbonate and organic matter was oxidized to CO₂ and stored in the atmosphere (Holland 1984), as happened on Venus, the resulting 60–100 bar CO₂ greenhouse could have produced surface temperatures to 180–230 °C even as far back as 4.4 Ga (Abe 1993). If pCO₂ values were reduced to around 0.5 bar (still a 1500-fold increase from modern values) by massive silicate weathering and carbonate sequestration in oceans as well as by

enhanced volcanism and plate recycling, estimates for Hadean-Eoarchean surface temperatures are reduced to near 0 °C. Was the early Earth warm or cold? Controversy prevails over the interpretation of proxy temperature data from isotopes of oxygen (Knauth 2005) and silicon (Robert and Chaussidon 2006; Marin Carbonne et al. 2014) in Precambrian oceans, temperature, and cherts. These data have been interpreted to indicate seawater temperatures above 50 °C back to about 3.5 Ga. Atmospheric models constructed to simulate conditions on the early Earth are inconsistent with the geochemistry of ancient sediments deposited in a hot ocean. Instead, model outputs for these atmosphere simulations usually call for temperatures at or below the freezing point of water. Hence, much more work remains to be done to resolve this fundamental discrepancy between model and experiment.

Late Heavy Bombardment and Its Effects

During the epoch of late accretion to the late Hadean and early Eoarchean Earth (4.5–3.9 Ga), meteoritic impacts modified geothermal, geochemical, and geomorphologic conditions at the surface. Large impactors, hundreds of kilometers in diameter, can transform a globally habitable Earth into a surface cauterized by a 100 m thick film of molten rock. However, only the largest of these impacts would have affected more than a hemisphere, leaving the rest relatively unaffected.

Almost all of our information about early bombardment of the inner solar system comes from studies of the surface of the Moon, but that has now changed with more information from the asteroid belt and dynamical simulations. Various objects in the Solar System preserve abundant evidence for an intense impact flux at some time between the formation of the crust of asteroid Vesta (4.53 Ga) and the outpourings of lava into the mare basins of the Moon (>3.1 Ga). Ages of recovered fragments of the ancient lunar highland crust returned during the Apollo program have been interpreted to represent either a short and intense ▶ “late heavy bombardment” (LHB) period at 3.9 Ga (Ryder 2002) or the tail end of an extended postaccretionary bombardment.

Some authors have argued that the absence of lunar impact melt ages older than about 3.9 Ga requires that the solar system was relatively quiet from the Moon-forming impact to the LHB (Ryder 2002). Independent verification of an LHB comes from studies of lunar meteorites that record impacts from the 3.9 Ga period (Cohen et al. 2000). If so, why was there a bombardment? The exact mechanism is unknown, but early gravitational resonance interaction between Jupiter and the other outer planets has been implicated (Gomes et al. 2005). The sources and tempo of bombardment, however, remain obscure. New work reveals a timeline that relates variably retentive radiometric ages documented from asteroidal meteorites to new dynamical models that invoke an early episode of planetesimal-driven giant planet migration after the dispersal of the protoplanetary disk (Mojzsis et al. 2019). We now know that a declining rate of impactors continue to strike the inner planets through a protracted monotonic decrease in impactor flux, in agreement with predictions from crater chronology.

Earth is a larger body than the Moon, with stronger gravity to attract bolides and more surface area to be struck. By inference from the well-preserved lunar and Martian records, Earth’s crust during the most intense bombardment phase of late accretion before about 4.3 Ga (Brasser et al. 2020) ought to have been pummeled to a molten state. Although basic features of such an impact environment have been investigated via numerical models, the specific consequences of these collisions for the crust and the overall effects they had (destructive or procreative) to the emergent biosphere are an area of intense current study (e.g., Genda et al. 2017). Numerical modeling studies of the consequences to the Earth of impacting after the Moon-forming event (ca. 4.53 Ga) show that temperatures planet-wide were never brought to levels necessary for global sterilization (Abramov and Mojzsis 2009).

Early Hydrosphere

Earth’s surface zone, from the top of the atmosphere to mid-crustal depths, has more than one ocean volume’s worth of liquid water (~0.03% of

Earth's mass). But uncertainty lingers over Earth's total inventory of water and the ultimate source of Earth's water also remains ill constrained: it could be from intrinsic outgassing during planetary growth of water supplied in accreting planetary material, or it could have come subsequently from accreting meteoritic or cometary matter ► [late veneer](#) (Albarède 2009). Probably all of these are correct. The availability and long-term stability of liquid water over geologic timescales is probably the determining factor that controls habitability of a planet's surface. Deciding whether Earth is relatively "dry" or "wet" as terrestrial planets go will depend on discoveries from future extrasolar systems by remote observations. Direct evidence for abundant surface water on Earth appears to extend as far back as the beginning of the geologic record.

Mildly deformed and metamorphosed volcanic and sedimentary rocks that formed subaqueously are found in 3.49 Ga rocks in the Pilbara craton of Western Australia and the Barberton greenstone belt of South Africa (Van Kranendonk 2006). However, all rocks older than about 3.6 Ga are highly deformed gneisses that have experienced pervasive metamorphism and recrystallization. The most ancient gneissic terranes consist of more than 90% of intrusive rocks and most of these are of granitoid (TTG) composition. These rock types, especially the tonalites and trondhjemites, are derived from Na-rich and K-poor melts of hydrated mafic (usually oceanic) crust following transformation into garnet amphibolite or eclogite. As with most (but not all) present occurrences of TTGs, these rocks probably formed in subduction zones (Martin et al. 2005, 2014). In older terranes such as the West Greenland Itsaq Gneiss Complex (Nutman et al. 1996), multiple generations of granitoids of different ages and compositions host enclaves and tectonized rafts ranging in size from meter to kilometer scale of yet older "supracrustal" rocks which constitute something less than 10% of the mapped outcrops. The oldest terrestrial rocks are found in the 4.03 Ga ► [Acasta Gneiss](#) Complex, but these deep-seated (7 km?) intrusive igneous protoliths do not convey direct information about the surface. Only when further discoveries are

made of pre-3.6 Ga gneisses and supracrustal enclaves will more direct information be revealed about the early Earth.

The oldest rocks with surviving volcanic and sedimentary structures indicative of a marine origin form a tiny amount of the dominantly amphibolite (metamorphosed basalt) rocks of the ca. 3.8 Ga Isua Supracrustal Belt which is part of the Itsaq Gneiss Complex. Within some low-strain zones of the amphibolites, clear pillow structures are preserved, and because such structures form when lavas erupt under water, they directly establish that liquid water was present when the Isua lavas erupted. At the Isua Supracrustal Belt, associated with these rocks are quartz-magnetite schists that in places are preserved as banded iron formations (BIF) with genuine sedimentary banding; such sedimentary rocks also formed in liquid water. The Isua Supracrustal Belt contains the oldest undisputed terrestrial record of a marine environment.

Of the other pre-3.8 Ga gneisses and amphibolites in Greenland, none has been more closely scrutinized than the ca. 3.85 Ga-old outcrops on the island of Akilia (Manning et al. 2006). Rocks on Akilia include the polyphase Itsaq Gneiss Complex with ages that span 3.87–3.62 Ga (Nutman et al. 1996). Unlike the Isua rocks, which encompass at least 200 km² of continuous exposure and preserve some primary structures, the gneisses on Akilia are very highly deformed. Although the Akilia association is widespread, with occurrences of enclaves throughout the southernmost part of the Itsaq Gneiss Complex, they are at much smaller scale and are less coherent than the Isua belt. At best, meter- to tens of meter-scale enclaves of amphibolites and ferruginous quartzites are present locally (Cates and Mojzsis 2006). Enclaves of Akilia quartz-magnetite-pyroxene schists have been interpreted as metasediments, and they share the trace element signatures of BIF from Isua and elsewhere (Manning et al. 2006). They preserve Fe isotope fractionations unlike igneous rocks and similar to Isua BIF (Dauphas et al. 2007). Several workers have proposed a minimum age of 3.83–3.85 Ga for the Akilia supracrustal rocks (Nutman et al.

1996; Manning et al. 2006), but this age, as well as the interpretation of these rocks as an originally volcano-sedimentary succession, has been stridently challenged.

Other localities with >3.7 Ga volcanic or sedimentary rocks are found in the northeasternmost margin of the Superior Province in the Nuvvuagittuq Supracrustal Belt (previously known as Porpoise Cove). The Superior Province in northern Quebec is dominantly composed of TTG and dioritic gneisses containing enclaves of older amphibolitized supracrustal rocks (Cates and Mojzsis 2009). As in West Greenland, these tend to comprise linear belts of metamorphosed sedimentary and extrusive igneous rocks that in rare cases preserve primary sedimentary and volcanic structures. Detailed mapping and geochronology of these units confirm a minimum age of 3.75 Ga for an 8 km² enclave of mafic and ultramafic amphibolites, quartz-magnetite BIFs, quartz-amphibole schists, and other possible detrital sediments at Nuvvuagittuq (Dauphas et al. 2007). On the other hand, Jack Hills zircon crystals, recorded the trace of interaction with liquid water, which is interpreted as an evidence in favor of oceans on Earth surface as early as 4.4 Ga (Mojzsis et al. 2001).

► **Plate tectonics**' mechanisms can be viewed as an adequate, but not exclusive, means of generating the ancient continental crust preserved in the West Greenland and northern Canada terranes cited above. Alternatively, ► **mantle** superplumes could have played at least a supporting role in the generation of this early crust. Future detailed studies of the oldest terranes will test the idea that plume's plate tectonics or some hybrid model can account for the structure and geochemistry of the oldest preserved crust.

Did Plate Tectonics Work Out in the Early Archean?

Within the most ancient terranes that have been mapped at the appropriate detail and which have been subjected to extensive geochronological studies, intrusive, volcanic, and sedimentary rocks of different ages are juxtaposed. Some authors have argued that this kind of geologic style preserved in West Greenland is a

consequence of a compressive regime and plate boundary processes that extended back to 3.8 Ga or even earlier in the Hadean (Korenaga 2008; Davies 2008). Like modern oceanic arc evolution, many ancient but much better-preserved terranes, such as the 3.5 Ga Pilbara craton, record permissive evidence of tectonic evolution from plate- or plume-related crust formation to episodic growth of continental crust through the emplacement of tonalites derived from partial melting of hydrated basalt (Martin et al. 2014). The granitoids intruded sequences of basalt with ferruginous-siliceous sedimentary layers, a scenario remarkably similar in both structure and chemistry to many contemporary island arcs above subducting oceanic slabs.

Did Plate Tectonics Exist in the Hadean?

Zircons older than 3.9 Ga are mostly found at Jack Hills and Mt. Narryer in the Narryer Gneiss Complex, Yilgarn craton, Western Australia (Froude et al. 1983; Compston and Pidgeon 1986). Others have been recovered from elsewhere in Western Australia (Wyche et al. 2004) and in scattered localities worldwide (e.g., Mueller et al. 1998; Paquette et al. 2015; Miller et al. 2018). Many of the most ancient Jack Hills' zircons contain inclusions of quartz, feldspar, muscovite, and other phases produced from silica-saturated igneous rocks, meaning that granites existed before 4.1 Ga (Hopkins et al. 2008). Low temperatures of formation, consistent with plate underthrusting, have been determined using titanium thermometry on >4.0 Ga Jack Hills' zircons (Watson and Harrison 2005). Many Hadean zircons also have isotopically heavy oxygen ($\delta^{18}\text{O}$ up to +7.3‰) which supports the view that melting of hydrated ► **crust** produced the pre-4.0 Ga granites and that some were possibly contaminated by subducted sediment (Mojzsis et al. 2001). Although the details of this hypothesis remain the focus of debate, the viewpoint of a hospitable, water-rich ► **Hadean** Earth leads to a number of predictions:

- Separation of crust into continental (granitic) and oceanic (mafic) styles prevailed since the earliest times.

- Conditions were conducive to the development of prebiotic chemistry and subsequently to the long-term sustainability of biological activity.
- Since the Hadean, actual preservation of Hadean zircons shows that Earth had crystallized its magma ocean and formed stable crust by 4.4 Ga and that no catastrophic impacts wholly destroyed that crust. Although the nature of the primordial crust and the composition of the source rocks of the 4.4–4.0 Ga zircons remain unresolved (Trail et al. 2007), there is now little doubt that the Hadean Earth could have supported life.

Finally, although no rocks and minerals are preserved from Earth's first 150 million years, there ought to be echoes of its prior existence. Recent work from both Nd and Hf isotope signatures from 4.4 to 3.5 Ga rocks and minerals provides evidence of planetary-scale events during the Earth's first 100 million years. These events that entailed major chemical fractionations in the mantle, perhaps as a consequence of an early magma ocean and the establishment of the proto-crust in the early Hadean, occurred prior to about 4.3 billion years ago or even earlier (Caro et al. 2006; Boyet and Carlson 2007; Blichert-Toft and Albarède 2008).

Definition

The surface of the Archean Earth was in many ways similar to that of today. Oceans covered most of the globe, but there were also regions of dry land. Oceanic crust could have been almost as thick as continental crust, mountain ranges were not very high, and parts of oceanic ridges and plateaus were emergent. Geological processes such as volcanism, erosion, and sediment deposition operated as now but were influenced by a lack of vegetation, higher ocean temperatures, and a hotter more aggressive, acidic atmosphere.

Overview

The total area covered by oceans was greater than today (Flament et al. 2008; Johnson and Wing 2019), and this, for two reasons. First, the volume of continental crust may have been less, if this crust had grown progressively through time (Benn et al. 2006). Second, the oceans were more voluminous because high temperatures in the mantle (Nisbet et al. 1993) destabilized hydrous minerals and drove water to the surface. Mountain ranges existed but were not as high as those of today were, because the continental crust was heated internally and rendered more ductile by more abundant radioactive elements. Continental crust was relatively thin, while oceanic crust, produced by high-degree melting of the hotter mantle, was thicker (Sleep and Windley 1982). The subdued topography, the limited contrast between the thicknesses of oceanic and continental crust, combined with bigger oceans, meant that much of the continental crust was probably flooded (Arndt 1998).

As during the more recent geological history, global temperatures waxed and waned. However, the Earth does not record periods of global glaciation before 2.5 Ga (Hoffman et al. 2017), the oldest, being also the most pronounced one, took place during the Proterozoic. Moreover, the O and Si isotopic compositions of Archean cherts suggest that ocean temperatures were commonly above 40 °C (Marin Carbonne et al. 2014). The atmosphere contained a little to no free oxygen but was rich in CO₂; rainwater was acid.

The normal cycle of erosion, transport, and deposition of sediment operated, but the rivers flowed through a landscape that was very different from that of today. The feature that most starkly distinguished the Archean and modern land surface was the lack of vegetation. Microbes no doubt colonized the subsurface and constructed biofilms (slime mats) that covered moist areas, but most of the landscape was a Martian vista of bare rocks and soil. The rate of erosion was enhanced by the lack of vegetation, high temperatures, and aggressive atmosphere but restrained by modest heights of mountain belts. Erosion was also more efficient due to greater tidal amplitude, as

consequence of a smaller Moon-Earth distance (Lathe 2004). Active volcanism covered much of the surface with lava flows or pyroclastic deposits.

The ► [oceanic crust](#) was composed of basaltic lavas like that of modern crust but more magnesian (picritic) in places (Sleep and Windley 1982). Parts of mid-ocean ridges and the summits of oceanic plateaus may have been emergent forming what might be called “melano (dark-colored)-continents.” The pelagic sediment that covered this crust was different from that of today. An absence of shell-forming organisms precluded the formation of biogenic calcareous or siliceous oozes; in their place were Si- or Fe-rich sediments that precipitated directly from the high-temperature seawater that contained high concentrations of these elements. Hydrothermal circulation of Si-charged seawater resulted in massive silicification of all near-surface rocks. Expulsion of fluids at hydrothermal vents led to the deposition of exhalative sediments variably composed of sulfides, sulfates, carbonates or silica minerals (Russell et al. 2005).

The earliest Archean coincided with the end of the ► [Late Heavy Bombardment](#), a time of massive meteorite impacts. The largest of these would have vaporized large expanses of the oceans and pulverized large parts of the continents, but their overall impact was local, not global.

Opinions differ concerning the surface environment in the Hadean. One school envisages a ► [cool early Earth](#) in which clement conditions reigned (Valley et al. 2002); another imagines a hellish environment in which periods of intense heating subsequent to meteorite impact alternated with global glaciation when the atmosphere budget of greenhouse gases was insufficient to counteract the weak luminescence of the young sun (Sleep and Zahnle 2001; Feulner 2012).

Earth-Like Atmosphere

John Lee Grenfell
German Aerospace Center (DLR), Berlin,
Germany

Definition

An earth-like atmosphere is one whose dominant constituents are molecular nitrogen and molecular oxygen. This definition encompasses therefore (i) the early Earth since the start of the Proterozoic period where atmospheric oxygen started to rise, (ii) the modern Earth, and (iii) theoretical studies in exoplanet science investigating hypothetical planets assumed to possess significant earth-like atmospheres and which orbit, e.g., different classes of main sequence stars or/and which are at different positions in the habitable zone.

Earth-Like Planet

► [Terrestrial Planet](#)

Eccentricity

Daniel Rouan
LESIA, Observatoire Paris-Site de Meudon,
Meudon, France

Definition

The eccentricity is a parameter (denoted by e) characterizing the orbit's shape for an object gravitationally bound to another one. It quantifies the amount by which the orbit deviates from a circle: $e = 0$ for a circle, $e = 1$ for a parabola, $e > 1$ for a hyperbola, and $0 < e < 1$ for an ellipse, where $e = c/a$, with c the distance from the center to a focus and a the semimajor axis. See Fig. 1 for an illustration of different values in the case of an ellipse. The eccentricities of planets belonging to the solar system are rather small, while a significant fraction of the discovered exoplanets exhibit large eccentricities, in excess of 0.3.

Eccentricity,

Fig. 1 Several examples of elliptical orbits with different eccentricities

Eclipse

David W. Latham¹ and Nader Haghighipour²

¹Harvard-Smithsonian Center for Astrophysics,
Cambridge, MA, USA

²Institute for Astronomy, University of Hawaii-
Manoa, Honolulu, HI, USA

Synonyms

[Eclipsing binary](#); [Primary eclipse](#); [Secondary eclipse](#); [Transit](#)

Definition

In an astronomical system, when orbits of two or more objects are viewed edge-on, the components periodically pass in front of each other, thus reducing the amount of light that reaches the observer. This phenomenon is known as Eclipse. If both components are stars, the system is called an eclipsing binary. Normally the deeper eclipse occurs when the cooler object passes in front of the hotter one. This is traditionally denoted by the primary eclipse. The secondary eclipse refers to the shallower event when the cooler component passes behind the hotter one. However, there can be interesting exceptions to this general pattern. For example, with highly eccentric orbits and modest inclinations, one or the other of the eclipses may not occur.

By convention, the eclipse of a star by a much smaller and cooler object such as a planet is called a ► [transit](#), while the passage of the planet behind the star is termed either an occultation or a secondary eclipse. Another interesting case is a binary consisting of a normal star and a ► [white dwarf](#). White dwarfs are small enough to produce transit-like events when they pass in front of the star. But, if they are young enough, they can be hotter than the star, thus producing a deeper eclipse when they pass behind the star.

Eclipsing binaries for which the spectra of both stars can be detected are especially valuable. In

these systems, an analysis of the light curve (the graphs of the variation of the intensity of the light received from the system in term of time) together with the spectroscopic orbit derived from the radial velocities of the two stars can yield the absolute mass and radius of each stellar component. If the spectrum of only one of the stars is detected (presumably that of the brighter one), then only the ratios of the masses and radii can be derived directly. Interestingly, the density of the primary star and surface gravity of an unseen companion can also be derived from the light curve and orbital solution. If the mass of the primary can be estimated from other observations, such as spectroscopy and/or parallaxes combined with stellar models, then the actual mass and radius of the secondary can be derived. Transiting planets are simply an extreme example of the case where only the spectrum of the primary star yields an orbital solution.

Ecological Niche

Felipe Gomez
Centro de Astrobiología (CSIC/INTA), Instituto Nacional de Técnica Aeroespacial, Torrejón de Ardoz, Madrid, Spain

Definition

Niche in ecology is a term which refers to the relational position of a species or population in an ecosystem (environment). It refers to the behavior of the population to any external input or relationship including resources, competitors, physical conditions, etc.

Ecology, History of

Stéphane Tirard
Centre François Viète d'Histoire des Sciences et des Techniques EA 1161, Faculté des Sciences et des Techniques de Nantes, Nantes, France

The word ecology comes from the ancient Greek *oikos*, house, and *logos*, science. It was coined by

E. Haeckel in 1866 and means the relationship between living beings and their environment. Toward the end of the nineteenth century, this relation became a research topic for botanists. For instance, in 1895, Eugen Warming was a pioneer of the study of the distribution of plants.

In 1935, G. Tansley created the word ecosystem, which he defined as the functional ecological unit. During the 1950s, E.P. and H.T. Odum, inspired by thermodynamics, developed central concepts, such as a theory of open systems and the notion of a dynamical equilibrium regulated by energy flows. That was the development of systemic ecology.

Ecosystem

J. Cynan Ellis-Evans
UK Arctic Office, Strategic Coordination Group, British Antarctic Survey, Cambridge, UK

Keywords

Abiotic · Biogeochemical cycles · Biological populations · Biotic · Environment · Physicochemical conditions

Definition

An ecosystem is part of the broad ► [environment](#), comprising of both physical (► [abiotic](#)) and interdependent biological (biotic) components, in which the community of living organisms continually interacts with all abiotic components (e.g., rock, water, air, soil, sunlight) through various interconnected relationships. The flow of energy within an ecosystem, manifested through cycling of materials between the biotic and abiotic components, defines its inherent trophic structure and biological diversity.

Overview

The ecosystem concept developed, as a more abstract replacement of the concept of community, out of theorizing in the 1930s on the organization and dynamics of natural systems. While a community is a group of populations of different organisms that interact with one another in a given ► [habitat](#) or area and are interdependent, an ecosystem is considered an area where living communities exchange materials "...with the whole complex of physical factors that form what we term an environment" (Tansley [1935](#)). Ecosystems are therefore essentially self-contained energy and nutrient cycles. An ecosystem can be long lived or temporary, and balance is a critical element of any viable ecosystem because disturbances and instability in its physical factors (e.g., rapid climate change) can threaten the existence of its component organisms. Ecosystems can be small or large, and the physical boundaries of an ecosystem can be defined as in a pond, or relatively blurred, as in the case of a marsh draining into a stream or river. Ecosystems are everywhere and the diversity is enormous on a planet such as Earth, and indeed we are still discovering environments (e.g., the deep subsurface, subglacial lakes) that harbor as yet barely researched ecosystems. Extreme environments on Earth provide analogues of possible extraterrestrial ecosystems. Potential locations include subsurface permafrost lithosols on Mars; the ice-covered ocean of the Jovian moon, Europa; the hydrocarbon lakes on Titan; or the subsurface water on Enceladus.

Effective Temperature

Daniel Rouan

LESIA, Observatoire Paris-Site de Meudon, Meudon, France

Definition

The effective temperature of a star is the temperature of a ► [blackbody](#) of the same radius as the

star and that would radiate the same total amount of electromagnetic power as the star.

Overview

Noted T_{eff} , the effective temperature is one of the fundamental parameters that characterizes a star. If P_* is the power radiated by a star of radius R , then T_{eff} is derived by applying the Stefan-Boltzmann law: $P_* = 4\pi R^2 \sigma T_{\text{eff}}^4$. Indeed a star is not actually a blackbody, as its [▶ emissivity](#) varies with wavelength; however, the effective temperature generally provides a fair approximation of the actual temperature of the stellar photosphere. This is so because at any wavelength, the radiation comes from a layer which is always on the *skin* of the star (the [▶ photosphere](#)) and, thus, at approximately a constant temperature. The effective temperature is directly related to the color of the star: the higher the temperature, the bluer the light emitted by the star. The effective temperature is one of the two parameters, with the stellar luminosity, used to build the classical HR diagram that permits astronomers to classify stars. The effective temperature of the Sun is 5,780 K, while it is 40,000 K for an O star and 3,000 K for an M star. The term has been extended to planets, with a similar definition, but, there, the effective temperature can sometimes be fairly different from the surface temperature. This is, for instance, the case of Venus, where the [▶ greenhouse effect](#) in the atmosphere (due to CO_2) blocks the infrared outward radiation imposing a ground temperature of 735 K, much higher than the effective temperature of 225 K, in order to maintain the balance between the absorbed solar flux and the emitted thermal radiation. Note that the effective temperature depends on the reflectivity, or albedo, of the planet: the larger the [▶ albedo](#), the lower the effective temperature.

Ejecta

Daniele L. Pinti

Geotop, Research Centre for the Dynamics of the Earth System, Université du Québec à Montréal, Montreal, QC, Canada

Synonyms

[Pyroclastics \(in volcanology\)](#)

Definition

Ejecta is solid or liquid material ejected from a source region. In geology, two types of ejecta exist: impact ejecta and volcanic ejecta. Impact ejecta is solid, liquid, or vaporized rock debris expelled from a crater during the excavation stage of a meteoritic impact. This ejecta can be dispersed around the crater (proximal) and form specific patterns or partially build the crater rim. Distal ejecta, such as tektites and microtektites, spreads to much greater distances and can eventually cover the entire planet, as in the case of the Chicxulub crater.

The volcanic ejecta is rock debris ejected by an explosive volcano and normally grouped in the more general term *pyroclastics*. In astrophysics, ejecta is the gaseous material expelled from a star, either quiescently (e.g., in coronal mass ejection or through the wind of an evolved star, like a red giant or an AGB star) or in a stellar explosion like in a supernova or nova.

Ejection, Hyperbolic

Sean N. Raymond
Laboratoire d'Astrophysique de Bordeaux,
CNRS, Université de Bordeaux, Bordeaux,
France

Definition

Hyperbolic ejection is the removal of an object from a gravitational system (e.g., a planetary system) on a hyperbolic ► [orbit](#), so that the object is permanently lost from the system. This is caused by an increase in a body's orbital energy that exceeds the gravitational binding energy of the system. In planetary systems, the increase in orbital energy usually comes from a close encounter with a massive planet. Objects that are ejected from planetary systems are thought to include a large number of ► [planetesimal](#)-sized bodies (asteroids and comets), a small number of ► [planetary embryo](#)-sized bodies, and, in some cases, fully grown terrestrial, ice giant, or gas giant planets.

Electric Discharge

Jeffrey Bada
Scripps Institution of Oceanography, La Jolla,
CA, USA

Synonyms

[Spark discharge](#)

Definition

An electric discharge is the release and transmission of electricity in an applied electric field through a medium such as a gas. Several types of electric discharges occur naturally on Earth (American Geophysical Union, National Research Council (U.S.). Geophysics Study Committee 1986):

1. Atmospheric lightning, which is thought to be caused by the frictional generation, and separation, of positive and negative charges on ice and dust particles. As the charge on these particles builds up, the result is the often-spectacular discharge of electricity known as lightning. On average, there are 50–100 lightning strikes per second on Earth with most of the activity taking place in equatorial and northern latitudinal regions.
2. Corona discharges, which are caused by an electrical discharge produced by the ionization of the surrounding atmosphere, generating a luminous plasma (sometime referred to as St. Elmo's fire, a term used by sailors to describe the glow observed at the top of a

ship's mast during a thunderstorm). Unlike lightning, which is instantaneous and transient, coronal discharges are less brilliant, can last for a significant period of time (minutes or more), and occur over a large surface area. Continuous corona discharges have been observed on the nose cones of airplanes during thunderstorms.

3. Volcanic lightning, which is ubiquitous in most volcanic eruptions, especially water-rich eruptions. The cause of the lightning is not completely understood but is thought to be the charging of ash particles by frictional processes and the ionization of gases expelled in the eruption. Volcanic lightning has been observed to be nearly continuous during an eruption.

Overview

Electrical discharges have also been observed in the atmospheres of other bodies in the solar system (Aplin 2006). Lightning has been detected during observations of Jupiter and Saturn, and the NASA/ESA Cassini/Huygens mission has tentatively detected lightning in the atmosphere of Titan.

Electric discharges on Earth, and by implication elsewhere, play an important role in various aspects of atmospheric chemistry. On the present-day Earth, the major products of lightning acting on the gases in the atmosphere are NO, along with lesser amounts of ► [ozone](#). On the primitive Earth, a possible reducing atmosphere containing nitrogen and methane would have had HCN as the major product. In contrast, with a neutral nitrogen-carbon dioxide-rich primordial atmosphere, the major product would have been a mixture of NO and CO, as well as ammonia and HCN (Cleaves et al. 2008).

In the hydrogen-rich Jovian atmosphere, the products produced by lightning are much more diverse and include, besides HCN, low molecular weight hydrocarbons and formaldehyde. Lightning in the solar nebula may have also been important in the synthesis of reduced species of importance in prebiotic chemistry.

Electric discharges were first used in the context of astrobiology research in the 1952 Miller-Urey Experiment (Miller 1953) in which a spark was passed through a mixture of methane, ammonia, hydrogen, and water, simulating the action of lightning acting on what was then thought to be the composition of the primitive atmosphere. This experiment ultimately yielded amino acids, suggesting a facile route from simple environmental processes to the building blocks of modern organisms.

Electromagnetic Radiation

Daniel Rouan
LESIA, Observatoire Paris-Site de Meudon,
Meudon, France

Definition

The expression electromagnetic radiation designates the energy that is transported in the form of a propagating wave made of two perpendicular components, one an electric field and the other a magnetic field, which oscillate at the same frequency. This description applies to light in all its forms: radio waves, infrared, visible light, ultraviolet, x-rays, and gamma rays. It is by far the most important vector of information reaching us that comes from the universe and the objects it contains. Different physical processes give rise to electromagnetic radiation and are generally classified as thermal (resulting from the thermal motion in a medium), nonthermal radiation (synchrotron), or quantized (transitions between levels of energy in atoms, molecules, or nuclei).

Synonyms

[Electron transport chain](#)

Definition

Electron transport refers to the transfer of electrons from an initial donor (reducing substance) to a final acceptor (oxidizing substance) across different intermediaries, which takes place in biological membranes. Electron transport processes are usually associated with respiratory and photosynthetic processes.

Overview

The most common ways by which living organisms obtain energy from their surroundings is by the ► [oxidation](#) of external electron donors (chemotrophic organisms) or by the absorption of electromagnetic radiation (phototrophic organisms). In both cases, the energy translation mechanisms take place in membranes (the cytoplasmic membranes in the case of prokaryotes or subcellular particles such as mitochondria and chloroplasts in the case of eukaryotes). In the translation process, an electron transport takes place from a substance, which is an initial ► [electron donor](#) to a final acceptor, and since the ► [redox potential](#) of the donor is more negative than that of the acceptor, the global process is exergonic. This oxidation-reduction process takes place across a series of intermediaries (► [Electron Carrier](#)), which are not free in the intracellular medium as the majority of them form highly structured complexes inserted in the membranes. Therefore, the transfer of electrons that takes place between the different components does not occur using the conventional mechanism that takes place in the oxidation-reduction reactions of a homogenous system in dissolution. Instead, a directional electron transport takes place along the membrane and, in some cases, a transverse one as well. This explains how energy coupling between an oxidation-reduction reaction and a transport phenomenon is possible, as first, the free energy released by these processes is used to produce a proton transport against the gradient across the membrane, and then the proton ► [electrochemical potential](#) gradient is translated, by means of processes that also take place in the membrane, in ► [ATP](#).

For many years, the mechanism whereby electrons are transferred between the different electron carriers, which are frequently separated from each other when the structure of the complexes is greater than 10 Å, has been the subject of much debate. However, there is growing experimental and theoretical evidence that suggests that on some occasions the transport may be brought about by the “tunnel effect.”

The molecules that take part in the electron transport are quite ubiquitous. The most common molecules are cytochromes, quinones, iron-sulfur proteins, and flavoproteins. In addition, chlorophylls and pheophytins are involved in ► [photosynthesis](#).

Electrophoresis

Adrienne Kish
Institut de Génétique et Microbiologie, Université Paris-Sud 11, Orsay Cedex, France

Definition

Electrophoresis is the migration of charged molecules (for example ► [nucleic acids](#) or ► [proteins](#))

through a medium according to charge and molecular size as a consequence of an applied electric current and interactions with the medium. It is used as an analytical technique to separate molecules by charge, size, or binding affinity. Parameters including matrix composition and concentration, ionic strength, electrical current strength and field angle, and migration time can be varied. Electrophoretic methods commonly employed include capillary electrophoresis (CE), gel electrophoresis (GE), and pulsed-field gel electrophoresis (PFGE) for separation of chromosomal DNA; denaturing and/or temperature gradient gel electrophoresis (DGGE/TGGE) for separation according to sequence; polyacrylamide gel electrophoresis (PAGE) and SDS-PAGE for separation of proteins in their native and denatured conformations, respectively; and isoelectric focusing (IEF) and 2D electrophoresis for separation of proteins by isoelectric point with or without PAGE first.

Elemental Depletion

Steven B. Charnley
Solar System Exploration Division, Code
691, Astrochemistry Laboratory, NASA Goddard
Space Flight Center, Greenbelt, MD, USA

Definition

Elemental depletion denotes the difference in elemental composition of an astronomical

source relative to some standard of reference, usually the Sun. Lines of sight through the local interstellar medium indicate much lower abundances of many chemical elements compared to the solar composition. This is largely due to the differential incorporation of these elements into interstellar dust grains. Different lines of sight through diffuse clouds show different depletions.

History

The definition of “cosmic abundances” also takes account of the relative abundances in carbonaceous chondrites, which generally correlate well with those in the solar photosphere (Anders and Grevesse 1989; Przybilla et al. 2008) apart from the most volatile elements such as hydrogen and helium.

Enantiomeric Excess

Robert Hazen

Geophysical Laboratory, Carnegie Institution of
Washington, Washington, DC, USA

Synonyms

[Chiral excess](#); [Evolutionary Tree](#)

Definition

Enantiomeric excess (*ee*) is a measure of the deviation of a mixture of ▶ [chiral](#) (i.e., handed) molecules from the equimolar (or “racemic”) state. Enantiomeric excess is usually expressed as a percent; if D and L are the amounts of two chiral molecules, the enantiomeric excess is given as

$$ee = [(D - L) / (D + L)] \times 100$$

Thus, the *ee* of a 60:40 mixture of D:L is 20 – a value that can be thought of as a mixture with 20 % pure D plus 80 % racemic mixture; furthermore, *ee* equals 0 and 100 for racemic and chirally pure mixtures, respectively.

An enantiomeric excess can be measured in a number of ways, including specific optical rotation or chromatography with a chiral column. The enantiomeric excess is important in characterizing the purity of chiral pharmaceuticals and other chiral products. Many models of the origins of life postulate the local and/or global development of enantiomeric excesses in mixtures of amino acids or other biomolecules and their subsequent chiral amplification, as a prelude to life's ► [homochirality](#).

An enantiomeric excess has been reported in ► [carbonaceous chondrites](#) for some organic compounds, including amino acids (see ► [Chirality](#)).

Encapsulated Bioburden

J. Andy Spry
SETI Institute, Mountain View, CA, USA

Synonyms

[Embedded bioburden](#)

Definition

In planetary protection, the term “encapsulated ► [bioburden](#)” is used to indicate the viable microorganisms that are trapped inside nonmetallic spacecraft materials. They can be, for example, in the adhesive for honeycomb structures, the conformal coating of electronic boards, or in the matrix of a material itself. The term embedded bioburden can be used as a synonym, although “embedded” does not carry the same emphasis that the microorganism is isolated from the point of view of restricting water vapor loss, compare to “encapsulated.”

A spaceflight project may choose to directly measure the number of microorganisms present in a specific material, or use specification values as a conservative estimate of the number of microorganisms present. NASA and ESA have established consensus specifications describing the number of microorganisms that are assumed to be present in a variety of materials manufactured or prepared under defined environmental cleanliness conditions.

Encapsulation of a microorganism in a material matrix is thought to reduce the rate of water loss during heat sterilization processes (relative to surface bioburden) that is one of the causative factors for cell death during DHMR. The lethality of DHMR processes on encapsulated bioburden is

taken as one-tenth the lethality for exposed bioburden.

Saturn’s satellites

Definition

Enceladus is one of the mid-sized icy satellites of Saturn (500 km in diameter). It was discovered by William Herschel in 1789. Its distance to Saturn is 238,100 km or about 4 Saturnian radii. Its density is 1.0 g/cm³, corresponding to a bulk composition of water ice. With an albedo of 0.9, Enceladus is the brightest object known in the solar system; such a high albedo results in very low surface temperature (~70 K). Enceladus is best known for its plumes emanating from the south pole probably as an expression of the global salty ocean underneath the surface, which makes this satellite one of the most promising habitable environment in the solar system.

Overview

The exploration of Enceladus started with the Voyager missions. The first images of Voyager 1, taken in December 1980, already indicated a bright and young surface with relatively few

craters. Voyager 2, in August 1981, not only confirmed this result but also provided evidence for tectonic activity, which was totally unexpected on such a small object. These results raised the interest of scientists who considered Enceladus as a prime objective for the Cassini mission.

The exploration of Enceladus by Cassini started in 2005 with a series of flybys; the closest ones took place in March 2005 and July 2005, with respective distances of 501 and 172 km. Most of Enceladus' surface is covered with impact craters distorted by viscous relaxation and also by a more recent tectonic activity. Cassini images showed several different tectonic features: linear faults, curved stripes, and rifts (called "*fossae*") of over 200 km in length, 10–15 km in width, and 1 km in depth.

In addition, the Cassini instruments discovered at the South Pole a new region, previously unobserved, different from the northern hemisphere, which was rather smooth. This region, which extends southward up to a latitude of about 55S, is crater-free with many tectonic fractures and faults. The Cassini camera discovered therein four large faults distant from each other by about 35 km; they are up to 130 km in length, 2 km in width and 0.5 km in depth. They are known as the "tiger stripes" and are the youngest structures observed on the satellite. The Visible and Infrared Mapping Spectrometer of Cassini (VIMS) detected crystalline ice in this region, which indicates a very young origin (less than 1000 years): if older, the water ice would have been transformed into amorphous ice by the solar UV radiation. The frontier between the South Pole region and its surrounding is marked by parallel cliffs and valleys.

After the Voyager encounters, it was already proposed that cryovolcanism could be active on Enceladus thus accounting for its recent resurfacing. In addition, such a cryovolcanism would provide a source for the E-ring of Saturn which is located exactly at the same orbital distance as Enceladus. These hypotheses were fully confirmed by the Cassini observations in July 2005 and later on. First, observations by the magnetometer of Cassini showed, in the vicinity of Enceladus, a deviation of Saturn's magnetic field lines which

could be attributed to the interaction between this magnetic field and ionized particles surrounding the satellite. In addition, ultraviolet spectra recorded during a stellar occultation by the UVIS instrument showed a localized atmosphere, mostly made of water vapor around the South Pole. Simultaneously, the Cassini Ion and Neutral Mass Spectrometer (INMS) detected H₂O, but also N₂ and CO₂ in the cloud surrounding the South Pole. Finally, the Cosmic Dust Analyzer (CDA) detected near the tiger stripes microcrystals of water, similar to those of the E-ring, thus confirming Enceladus as the main provider of material in the E ring (Fig. 1).

Because of the low gravity field of Enceladus, the atmosphere (in the form of a torus) surrounding the South Pole cannot be stable and must be continuously replenished. The most likely mechanism for feeding this atmosphere is cryovolcanism through the tiger stripes. This also accounts for the temperature excess of about 15 K measured by the Composite Infrared Spectrometer (CIRS) around the tiger stripes. In November 2005, a visual confirmation was brought by the camera of the Cassini orbiter which observed jets of icy particles above the South Pole region.

Enceladus, Fig. 1 Enceladus as observed by the Voyager spacecraft. (©NASA)

Since 2005, repeated flybys have allowed scientists to accumulate data about the surface structure of the South Pole, the geysers, and the composition of the plumes. In addition to H_2O , N_2 , CO_2 , and CO , other simple and complex hydrocarbon chains have been identified. The presence of nitrogen has been interpreted as a dissociation product of NH_3 , which suggests the possible presence of liquid NH_4OH associated to H_2O under the surface of Enceladus. Enceladus' cryovolcanism is believed to be the feeding mechanism for the E-ring of Saturn, located at the same orbital distance.

In June 2009, the Cosmic Dust Analyzer has identified sodium salt (NaCl), in the icy grains which compose the E-ring. This constitutes a strong argument in favor of the presence of a salty water ocean below the satellite's surface. The presence of salts and carbonates in the geyser products suggests that such a liquid ocean of water could be in direct contact with a silicate core, which could have important implications for astrobiology. In 2017, the Ion and Neutral Mass Spectrometer of Cassini has detected molecular hydrogen in the plumes of Enceladus. Its origin could be due to the reaction of water with minerals and organics at the transition region between the water ocean and the solid surface; such a reaction (called serpentinization) is actually observed in terrestrial hydrothermal vents. The presence of dihydrogen in the plumes of Enceladus might be an indication for the presence of hydrothermal vents in Enceladus also.

What could be the origin of the internal energy that drives cryovolcanism on Enceladus? Solar energy which works for our planet is not effective at almost 10 AU. Tidal effects linked to the orbital resonance of Enceladus with Dione (another icy satellite of Saturn) could generate some internal energy, however, by far not enough to account for tectonic activity. According to some scientists, Enceladus, as other icy satellites of Saturn, might have formed very quickly. As a result, the satellite would have acquired a differentiated structure with a silicate core and an ice mantle. Subsequent radioactive and tidal heating would have raised the inner temperature enough to melt the icy mantle and part of the core, possibly

creating magma chambers which would feed cryovolcanism.

The water torus of Enceladus has been detected using the HIFI heterodyne spectrometer of the Herschel space observatory, which measured the water content along the line of sight and a very low temperature (16 K). From estimates of the water influx rate on Saturn and Titan, it was found that the water torus of Enceladus was probably the main source of stratospheric water for Saturn, and possibly for Titan as well. Future in situ investigations for both of Saturn satellites are necessary to precisely describe the habitability potential of these two worlds.

Endergonic

Jacques Reisse

Université Libre de Bruxelles, Brussels, Belgium

Definition

An endergonic reaction is one that requires ► [free energy](#) to proceed. An example of an endergonic reaction of biological interest is ► [photosynthesis](#). Photosynthetic organisms conduct this reaction by using solar photons to drive the reduction of carbon dioxide to glucose and the oxidation of water to oxygen. The free energy change during a chemical reaction or a physical transformation which takes place at constant pressure is described by the familiar ΔG symbol where G is the Gibbs free energy. By definition, ΔG is positive for an endergonic process (and negative for an ► [exergonic](#) process). When the reaction takes place at constant volume, the free energy change is described by the symbol ΔF , where F is the Helmholtz free energy.

Endogenicity

Nicola McLoughlin

Department for Geology, Rhodes University,
Makhanda (Grahamstown), South Africa

Keywords

Biosignatures · Contamination

Synonyms

[Indigenous](#)

Definition

A component that may be textural, chemical, mineral, or biological and that formed within the host material. For example, a mineral phase or organic structure found in a rock that is indigenous to that rock and not derived from external sources. Endogenicity concerns the source of a component with respect to space and this differs from syngenetic that concerns the source of a component with respect to time.

History

Traditionally, the term endogenetic has been used in geology to refer to processes originating below the Earth's surface as opposed to exogenetic that describes geological processes acting at or near the Earth's surface. This definition is here modified for the investigation of astrobiological samples obtained from a range of planetary surfaces and to operate at all observational scales from the field outcrop, hand sample to microscope.

Overview

A component formed within the host material that is indigenous to that sample and formed in a closed system. Endogenetic components are not sourced from interactions with external environments – such components are termed exogenous. Most often, endogenetic components are also syngenetic and formed at the same time as the host material but not always. For example, diagenetic and metamorphic phases produced by changes in pressure and temperature after formation of the host rock are endogenetic to that system (provided it was closed to fluid flow) but are not syngenetic, because they formed later in time. Often, exogenous components can be readily recognized because they occur in younger cross-cutting veins or the alteration rims of, for example,

meteorites and are derived from interactions with the terrestrial atmosphere or surface.

To demonstrate the endogenicity of a component requires its composition, structure, and context to indicate an origin from within that system. For instance, organic material found in a rock should occur in primary mineral phases or sedimentary fabrics; have an isotopic fingerprint that is distinct from externally sourced, migrating organic material; and exhibit a crystallinity and/or reflectance that is compatible with the thermal maturity of the host rock. One way to demonstrate this for carbonaceous material is to show that the Raman spectra of the candidate biosignature and host rock match, indicating that they have experienced the same degree of thermal alteration (Javaux et al. 2010). In addition, carbon isotopic measurements made both in-situ and on extractable phases can be used to characterize and distinguish endogenous from exogenous pools of organic material (Rasmussen et al. 2008). Fabric investigations are also crucial to eliminate exogenous components that are hosted by younger, possibly meta-stable phases produced by, for example, hydrothermal alteration, or weathering near the planetary surface and occur near cross-cutting features or external surfaces (Pinti et al. 2009). In meteorites, for example, it has been shown by biological staining and epifluorescence microscopy that terrestrial microbial hyphae can rapidly colonize the interior (Toporski and Steele 2007). Thus storage and handling protocols are essential to protect endogenous remains collected by sample return missions or delivered by impactors. Lastly, emerging nanoscale techniques for observing the interface between a candidate biosignature and host material can help to understand their preservational history and provide a further tool for assessing endogenicity (Wacey et al. 2008; Thomas-Keptra et al. 2009; Bernard et al. 2007).

Endogenous

Daniele L. Pinti

Geotop, Research Centre for the Dynamics of the Earth System, Université du Québec à Montréal, Montréal, QC, Canada

Synonyms

[Endogenetic](#)

Definition

In geology, endogenous (from Greek *endon*, within) is an adjective which refers to all processes produced in the interior of a telluric planet – such as tectonics, volcanism, and metamorphism –

but that can have subsequent effects on the surface of the planet itself. An example is the mantle convection which drives the movement of tectonic plates at the surface of the Earth. The main source of energy of endogenous geological processes is the heat produced by the radioactive decay of elements U, Th, and K and the residual heat from planetary accretion.

Amino acids · Formaldehyde · Hydrogen cyanide · Hydrothermal systems · Lipids · Organic molecules · Prebiotic chemistry · Primitive atmosphere

Synonyms

[Building blocks of primitive life](#)

Definition

Life, defined as an open chemical system capable of self-reproduction and evolution, is thought to have originated from reduced organic matter in water. Carbon was available as gaseous compounds in the primitive atmosphere, either oxidized as carbon monoxide and carbon dioxide or reduced as methane. When subjected to energy sources (UV, heat, electric discharges, cosmic rays, shock waves) and mixed with water and ammonia or nitrogen, these gases generate hydrogen cyanide and formaldehyde that lead to many of the building blocks of life, such as amino acids.

Deep-sea hydrothermal systems may also represent an environment for the synthesis of prebiotic organic molecules.

Overview

It is generally believed that life on Earth arose in liquid water about 4 billion years ago. It is likely that the ingredients of primitive life were organic molecules based on carbon and hydrogen atoms associated with oxygen, nitrogen, and sulfur. The simplest sources of carbon susceptible to lead to prebiotic organic molecules are gaseous, that is, carbon dioxide, carbon monoxide, and methane. A prebiotic environment must produce reduced organic molecules in which carbon is dominantly associated with hydrogen rather than oxygen.

Production of Organics in the Atmosphere

Oparin (1924) suggested that the small reduced organic molecules needed for primitive life were formed in a primitive atmosphere dominated by methane. The idea was tested in the laboratory by Miller (1953) who exposed a mixture of methane, ammonia, hydrogen, and water to spark discharge and silent electric discharge. In his initial experiment, he obtained three amino acids (glycine, alanine, and β -alanine) via the intermediary formation of hydrogen cyanide and aldehydes. More generally, simple gaseous molecules, like CH_4 , H_2 , NH_3 , and H_2O , require a supply of energy (UV, heat, electric discharges, cosmic rays, shock waves) to react with each other. They generate compounds like formaldehyde and hydrogen cyanide that store chemical energy in their double and triple chemical bonds, respectively. The possible sources of atmospheric synthesis, including electric effects, solar UV, and impact shocks, have been reviewed by Chang (1993).

Miller's laboratory synthesis of amino acids occurs efficiently when a reducing gas mixture containing significant amounts of hydrogen is used. However, the actual composition of primitive Earth's atmosphere is not known. The dominant view in recent years is that the primitive atmosphere consisted mainly of CO_2 , N_2 , and H_2O along with small amounts of CO and H_2 (Kasting and Brown 1998; Catling and Kasting

2007). Only small yields of amino acids are formed in such a mixture (Schlesinger and Miller 1983; Miller 1998). Recent studies show that the low yields previously reported appear to be the outcome of oxidation of the organic compounds during hydrolytic workup by nitrite and nitrate produced in the reactions. The yield of amino acids is greatly increased when oxidation inhibitors, such as ferrous iron, are added prior to hydrolysis, suggesting that endogenous synthesis from neutral atmospheres may be more important than previously thought (Cleaves et al. 2008). Additionally, 22 amino acids and 5 amines were obtained when reanalyzing archived samples of experiment run by Miller and simulating production of organic molecules in volcanic gases by lightning. The volcanic apparatus experiment suggests that, even if the overall atmosphere was not reducing, localized prebiotic synthesis could have been effective in volcanic plumes (Johnson et al. 2008). Unreported H₂S-containing experimental samples were also found and analyzed and were composed of numerous organosulfur compounds (Parker et al. 2011a, b, c). The H₂S samples were analyzed by high-performance liquid chromatography with fluorescence detection (HPLC-FD) and ultraperformance liquid chromatography-fluorescence detection with time-of-flight mass spectrometry. Miller's H₂S experiment synthesized 23 amino acids and 4 amines. Many non-protein amino acids, including several rare or absent, in biology were detected.

The atmospheric formation of glycolaldehyde, a key RNA precursor, has been investigated using a one-dimensional photochemical model. Maximum atmospheric production of glycolaldehyde occurs when the CH₄:CO₂ ratio is close to 0.02. The total atmospheric production rate remains small, only 1×10^7 mol yr⁻¹. Additional production or concentration mechanisms for glycolaldehyde or alternative formation mechanisms are needed (Harman et al. 2013).

The escape of hydrogen from the early Earth's atmosphere has recently been reevaluated (Tian et al. 2005). It may have occurred at rates slower by two orders of magnitude than previously thought. The balance between slow hydrogen escape and volcanic outgassing could have maintained a hydrogen mixing ratio of more than

30%, thus making endogenous organic synthesis more robust than previously thought.

Intense bombardment probably caused some chemical reprocessing of the Earth's primitive atmosphere by impact shock chemistry. An indication of the number and timing of the impacts onto the early Earth can be obtained by comparison with the crater record of the Moon, which records impacts from the earliest history of the solar system (Ryder 2003). Because of the larger size of the Earth and its greater gravitational pull, about 20 times as many impacts would have occurred on the early Earth as on the Moon. Computer modeling of impact shock chemistry shows that the nature of the atmosphere strongly influences the shock products (Fegley et al. 1986). A neutral CO₂-rich atmosphere produces CO, O₂, H₂, and NO, while a reducing CO-rich atmosphere yields primarily CO₂, H₂, CH₄, HCN, NH₃, and H₂CO. The last three compounds are particularly interesting for prebiotic chemistry since they can lead to amino acids via the Strecker synthesis. However, a CO-rich primitive atmosphere may be unlikely due to the instability of CO to photolysis. In laboratory experiments, a gas mixture of methane, ammonia, and water subjected to shock heating followed by a rapid thermal quenching yielded the amino acids glycine, alanine, valine, and leucine (Bar-Nun et al. 1970). Here again, the gas mixture used does not represent a realistic primitive atmosphere, which was probably dominated by CO₂. Laboratory simulations of shocks were also run with a high-energy laser. CH₄-containing mixtures generated hydrogen cyanide and acetylene, but no organics could be obtained with CO₂-rich mixtures (McKay and Borucki 1997).

Submarine Hydrothermal Systems

The reducing conditions in hydrothermal systems may have been an important source of biomolecules on the primitive Earth (Baross and Hoffman 1985; Holm and Andersson 1998, 2005). The reducing environment results from the flow of substances dissolved in seawater passing inorganic compounds present in very hot crustal material that reduce compounds in the seawater. These reduced compounds flow out of the hydrothermal system, and the inorganic sulfides formed

precipitate when they mix with the cold (4 °C) ocean water. For example, hydrocarbons containing 16–29 carbon atoms have been detected in the Rainbow ultramafic hydrothermal system, Mid-Atlantic Ridge (Holm and Charlou 2001). Hydrothermal vents are often disqualified as efficient reactors for the synthesis of bioorganic molecules, because of the high temperature. However, the products that are synthesized in hot vents are rapidly quenched in the surrounding cold water, which may preserve those organics formed.

In laboratory experiments, one amino acid synthesis started with a mixture of hydrogen cyanide, formaldehyde, and ammonia, so it is not really a hydrothermal process (Hennet et al. 1992). The same holds for a reported hydrothermal synthesis of amino acids that used calcium metal, formaldehyde, ammonia hydrogen, and oxygen in different combinations to generate amino acids (Marshall 1994). Amino acids and polymers of amino acids are formed by the reaction of methane and nitrogen at 325 °C in “modified seawater” in a glass-lined vessel (Yanagawa and Kobayashi 1992). “Modified seawater” contains the principal metal ions present in seawater but at much higher concentrations so as to amplify the chemical processes catalyzed by the ions so they can be more easily detected. The role of the silicate and metal ions in this complex reaction mixture is not clear, and this system may not be a good model of a hydrothermal system.

The role of submarine hydrothermal systems in the synthesis of amino acids has been carefully examined (Aubrey et al. 2009). The results of experiments exploring the potential for amino acid synthesis at high temperature from synthetic seawater solutions of varying composition have been reported. The synthesis of amino acids was examined as a function of temperature, heating time, starting material composition, and concentration. Using very favorable reactant conditions (high concentrations of reactive, reduced species), small amounts of a limited set of amino acids are generated at moderate temperature conditions (~125–175 °C) over short heating times of a few days, but even these products are significantly decomposed after exposure times of

approximately 1 week. Although amino acids can be generated from simple likely environmentally available precursors under submarine hydrothermal system conditions, the equilibrium at high temperatures favors net amino acid degradation rather than synthesis, and that synthesis at lower temperatures may be more favorable.

The Role of Minerals

Clay minerals are formed by water weathering of silicate minerals. As soon as liquid water was permanently present in the surface of the Earth, clay minerals accumulated. The importance of clay mineral in the origins of life was first suggested by Bernal (1949). The advantageous features of clays for Bernal were their ordered arrangement, their large adsorption capacity, their shielding against sunlight, their ability to concentrate organic chemicals, and their ability to serve as polymerization templates. Since the seminal hypothesis of Bernal, many prebiotic experiments have been run with clays (Ponnamperuma et al. 1982; Brack 2006; Negron-Mendoza et al. 2010).

Since during the Hadean to early Archean period (4.5–3.5 Ga) the surface of the Earth’s crust was predominantly composed of basalt and komatiite lavas, Meunier et al. (2010) considered that the composition of these rocks favored the crystallization of Fe-Mg clays rather than that of Al-rich ones (montmorillonite). It is assumed that every square meter of basalt or komatiite rocks was punctuated by myriads of clay-rich patches, each of them potentially behaving as a single chemical reactor which could concentrate the organics diluted in the ocean water. Considering the high catalytic potentiality of clays and particularly those of the Fe-rich ones (electron exchangers), it is probable that large parts of the surface of the young Earth participated in the synthesis of prebiotic molecules during the Hadean to early Archean period through innumerable clay-rich micro-settings in the massive parts and the altered surfaces of komatiite and basaltic lavas. This leads the authors to suggest that Fe-Mg clays should be preferred to Al-rich ones (montmorillonite) to conduct experiments for the synthesis of prebiotic molecules.

If the carbon source for life was carbon dioxide, the energy source required to reduce the carbon dioxide might have been provided by the oxidative formation of pyrite from iron sulfide and hydrogen sulfide. Pyrite has positive surface charges and bonds the products of carbon dioxide reduction, giving rise to a two-dimensional reaction system, a “surface metabolism” (Wächtershäuser 1994, 1998, 2007). Laboratory work has provided some support for this promising hypothesis. An early laboratory simulation of hydrothermal synthetic reactions is the reduction of carbon dioxide to organic sulfides at 75 °C in the presence of FeS and H₂S. Methyl- and ethyl-thiol were the principal thiols formed along with smaller amounts of others containing up to five carbon atoms. The CO₂ was also converted to CS₂ and COS (Heinen and Lauwers 1996). The direct reduction of CO₂ to acetic acid, acetaldehyde, ethanol, and smaller amounts of carbon compounds containing up to six carbon atoms was observed to take place at 350 °C and high pressure in the presence of magnetite (FeO:Fe₂O₃) and small amounts (2%) of water. The yields of organics decreased 10–100% when the proportion of water was increased to 90% (Chen and Bahnmann 2000). A similar inhibitory effect of large amounts of water was observed in the reduction of nitrogen to ammonia in the presence of magnetite and ten bars of CO₂ at 350 °C. The yield of ammonia decreased 10- to 100-fold when the water/iron ratio was increased from 0.5 to 6 (Brandes et al. 1998).

There are also reports of the reaction of CO in simulated hydrothermal systems. When a mixture of CO and CH₃SH was reacted with a combination of a NiS-FeS at 100 °C, acetic acid and its corresponding thioester were formed (Huber and Wächtershäuser 1997). This system was extended to the formation of keto esters at higher temperatures and pressures where CO is inserted into the thioester to form a keto thioester that in turn hydrolyzed to pyruvic acid (Cody et al. 2000). More recently, α -hydroxy and α -amino acids have been obtained under possible volcanic origin-of-life conditions by heating CO in the presence of nickel or nickel/iron precipitates with carbonyl, cyano, and methylthio ligands as carbon sources (Huber and Wächtershäuser

2006). However, the plausibility of the conditions used has been debated (Bada et al. 2007).

Endolithic

Angeles Aguilera
Laboratorio de Extremófilos, Centro de
Astrobiología (INTA-CSIC), Madrid, Spain

Definition

Endolithic refers to any ► [microorganisms](#) which are able to colonize and survive inside a rock.

Endoliths are classified into three different classes depending on the part of the interior of the rock that the organisms colonize: chasmoendoliths (chasm means cleft) are the organisms that colonize open spaces in the rock such as fissures and cracks; cryptoendoliths (crypto means hidden) are the organisms that colonize the interior of porous rocks; and euendoliths (eu which means true endolith) are the organisms that actively colonize the interior of the rock by forming tunnels with the shape of their bodies. These organisms are of extreme astrobiological interest because the interior of a ► [meteorite](#) can give shelter to endolithic organisms under the extreme conditions of an interplanetary voyage (► [lithopanspermia](#)).

Endosymbiosis

Amparo Latorre

Institute Cavanilles for Biodiversity and Evolutionary Biology, Universitat de Valencia, Valencia, Spain

Keywords

Bacteriocyte · Chloroplast · Endosymbiont · Mitochondria · Obligate mutualism · Symbiogenesis

Definition

Endosymbiosis is a symbiotic association in which one partner, generally a prokaryote symbiont, lives sequestered inside specialized eukaryotic host cells called bacteriocytes. The association is obligate for both partners.

Overview

Symbiogenesis, the evolutionary process of establishing a symbiotic association, has been one of the dominant forces in the early evolution of life on Earth. In 1967 Lynn Margulis postulated the serial endosymbiotic theory of eukaryotic ► [cell](#) evolution, currently accepted with respect to the origin of mitochondria and ► [chloroplasts](#) (Margulis 1993). These two eukaryotic ► [organelles](#) are beyond doubt the product of symbiogenic events between prokaryotes and primitive eukaryotes, as supported by many different types of genetic, biochemical, and phylogenetic evidence. The origin of mitochondria dates back to 2×10^9 years ago, whereas chloroplasts originated more than 1.2×10^9 years ago, because fossil red algae of that age have been found. DNA sequence comparisons and phylogenetic analyses have identified alpha-

proteobacteria and cyanobacteria as the bacterial groups to which the ancestors of mitochondria and plastids, respectively, belonged.

Nowadays, symbiotic associations have been documented in practically every major branch of the ► [tree of life](#), and this observation reinforces the role played by ► [symbiosis](#) in the emergence of evolutionary innovations in eukaryotes. Recently, the genomic era has opened the access to the characterization of the organisms involved in symbiosis, mainly those non-cultivable microbial endosymbionts, allowing the comparison among the different evolutionary innovations carried out by these bacteria on their way from a free-living lifestyle to varied stages of integration with their respective hosts (Dale and Moran 2006; Moya et al. 2008; McCutcheon and Moran 2012). Thus, endosymbiosis is an ongoing phenomenon in the evolution of life and played a key role in the origin and evolution of the eukaryotic cell.

In general, it is well established that endosymbiotic integration is a process that commonly changes profoundly the gene repertoire of the free-living ancestor. Depending on the type of symbiotic relationship (i.e., mutualistic or parasitic, facultative or obligate, etc.), age of the association, and host necessities (i.e., nutritional, defensive, waste recycling, etc.), the genetic and metabolic changes will be more or less dramatic (Wernegreen 2005; Moran et al. 2008).

We should not disregard the discovery of new instances of endosymbionts currently en route to become organelles or fully fledged eukaryotic compartments of bacterial origin (Nakabachi et al. 2006; Pérez-Brocal et al. 2006; Nowack et al. 2008; McCutcheon and von Dohlen 2011). Current “omics” (such as genomics, proteomics, or metabolomics) methodologies allow us not only to further unravel the steps toward the origin of the eukaryotic cell but also to assess the question of how much of the eukaryotic complexity originated through evolutionary innovations by symbiogenesis.

Endothermic

Jacques Reisse

Université Libre de Bruxelles, Brussels, Belgium

Definition

An endothermic reaction is a physical transformation which requires an energy supply if it takes place at constant volume or which requires an

enthalpy supply if it takes place at constant pressure. A familiar endothermic physical transformation is the evaporation of water. The enthalpy change (ΔH) or the energy change (ΔU) during an endothermic reaction or transformation is positive by definition.

Keywords

ATP · Bioenergetics · Chemical work · Electrochemical potential gradient · Electromagnetic energy · Energy transduction · Osmotic work

Definition

In physics, energy is defined as the capacity of a system to produce work. There are many forms of energy (e.g., mechanical, electrical, electromagnetic, chemical, etc.), and it is possible to convert some energy forms into others, with the condition that the energy is conserved.

History

A coherent theory on energy and its transformations was first advanced in the nineteenth century, chiefly as a consequence of the Industrial Revolution. The propounding of the fundamental principles (or laws) of thermodynamics established the basic rules for energy conversions.

Although important observations had already been made on the effect of energy on biological systems by the nineteenth century, it was not until the development of biochemistry in the twentieth century that energy conversion mechanisms in biological systems were explained. In 1941, Lipmann established that ATP is an energy currency in the biological system, while in 1961, Mitchell proposed the chemiosmotic hypothesis, which constitutes the base of all modern ► [bioenergetics](#). Nowadays, the majority of energy transduction processes at molecular level are well understood.

Overview

Ever since the Industrial Revolution, one of mankind's greatest challenges has been to find interconversion mechanisms for different energy forms (i.e. conversion of thermal, wind, electromagnetic, or atomic energy into mechanical or electrical energy). Although all energy forms are interconvertible, there are limitations with regard to the amount and quality of the energy released in a process that can be used in another one. For this reason, the total energy in a system is usually classified into different categories, such as internal energy, free energy, enthalpy, entropic contribution, etc. Of these, free energy is the only one that can be transferred from one process to another. Therefore, processes are classified as ► [endergonic](#) or ► [exergonic](#) depending, respectively, on whether they need or release ► [free energy](#) during their development.

Biological systems, when viewed as thermodynamic systems, are considered to be open systems, which means they can exchange matter and energy with their surroundings in order to maintain the dissipative structures, which characterize them. Basically, energy can be exchanged with the surroundings in two ways: through matter, by taking molecules from the environment whose catabolic processes (of degradation) release free energy, or by absorbing electromagnetic radiation. Furthermore, biological systems have mechanisms which can convert some forms of energy into

others, e.g., electromagnetic energy into osmotic energy, osmotic energy into chemical and mechanical energy, etc. These general mechanisms for the translation of energy within a biological system, which are the result of evolution and natural selection, constitute the field of study of bioenergetics and are truly astonishing. A general law governing energy coupling in biological systems states that they are not usually direct. Instead, they are produced through universal intermediaries or “energy currencies.” An exergonic process produces an energy currency which can then be used in an endergonic process. All of the energy currencies can be used to produce chemical work (production of molecules whose formation requires energy, in general anabolic processes), osmotic work (the transport of substances across membranes against their ► [electrochemical](#) potential gradients), or mechanical work (movement of flagella and cilia, contractile movements, etc.).

Energy Sources

Felipe Gomez

Centro de Astrobiología (CSIC/INTA), Instituto Nacional de Técnica Aeroespacial, Madrid, Spain

Keywords

Electron donors · Energy conservation · Fermentation · Photosynthesis · Radiation · Redox reactions · Reduced inorganic compounds · Reduced organic compounds · Respiration

Definition

Life implies work, in other words, it requires ► [energy](#). Metabolite transport across membranes, cellular ► [motility](#), or the biosynthesis of macromolecules are examples of cellular processes that require energy. Any living system relies on an external source of energy. The external sources of energy useful for living systems are only two: radiation and reduced chemical compounds. Living systems transform external energy sources into energy useful for cellular processes according to the thermodynamic law of energy conservation.

History

Peter Mitchell was awarded the 1978 Nobel Prize in Chemistry for his work in the description of the Chemiosmosis. Paul D. Boyer and John E. Walker were awarded part of the 1997 Nobel Prize in Chemistry for their clarification of the mechanism of ATP synthesis.

Overview

Energetic processes are basically related to oxidation-reduction reactions associated with the transformation of the energy sources. Energy sources are key elements for the classification of organisms. According to this, organisms can be classified as

chemotrophs if the external source of energy is chemical or phototrophs if it is radiation. Chemotrophs can be subdivided as chemoorganotrophs if the source of energy is a reduced organic compound (e.g., glucose, acetate), or chemolithotrophs if the source of energy is a reduced inorganic compound (e.g., ferrous iron, ammonia). The mechanisms by which organisms transform the external source of energy into cellular energy are three: ► [respiration](#), ► [fermentation](#), which is used by chemotrophs, and ► [photosynthesis](#), which is used by phototrophs. Cells can store the transformed energy as ► [proton motive force](#) (proton gradient) or in the form of energetic compounds like ► [ATP](#) or NADH. Some reactions or functions are driven by the proton motive force (transport of metabolites through the membrane, the rotation of the bacterial flagella); others require the use of ATP, such as the synthesis of macromolecules. An important achievement was the establishment of the chemiosmotic hypothesis coupling the ► [electron transport](#) in the respiratory chain with the generation of a proton motive force and the synthesis of ATP proposed by Peter Mitchell in 1961, and for which he was awarded the Nobel Prize.

Enthalpy

Jacques Reisse

Université Libre de Bruxelles, Brussels, Belgium

Definition

The enthalpy change is the heat produced or absorbed during a chemical or physical transformation taking place at constant pressure. The thermodynamic definition of enthalpy is $H = U + PV$, where H stands for enthalpy, U for internal energy, P for pressure, and V for volume.

Institut Cavanilles de Biodiversitat i Biologia Evolutiva, Universitat de València, València, Spain

Synonyms

[Glycolysis](#)

Definition

The Entner-Doudoroff (ED) pathway is the glycolytic pathway that allows to catabolize sugar acids, such as gluconate. Several enzymatic steps allow the conversion of six carbon sugar acids in two trioses that can be further metabolized through the universal lower part of the ► [Embden-Meyerhof-Parnas \(EMP\) pathway](#). This pathway is present in bacteria, but modifications have been described in all three domains of life. For example, the semi-phosphorylative ED pathway has been demonstrated in several anaerobic bacteria and in the halophilic archaea, whereas the non-phosphorylative ED pathway is found in some fungi and thermophilic and hyperthermophilic archaea. It has been suggested that the ED pathway is older than the EMP pathway.

History

The ED pathway was first discovered in 1952 in *Pseudomonas saccharophila* and in 1967 was shown to be also present in *Escherichia coli*.

Entropy

Jacques Reisse

Université Libre de Bruxelles, Brussels, Belgium

Definition

Entropy is a thermodynamic concept introduced in 1865 by Clausius. Entropy, represented by S , increases in any spontaneous processes (where ΔS is positive) taking place in an isolated system, i.e., a system which does not exchange matter or energy with its surroundings. If two gases are in

a constant-temperature box, initially separated by a partition and that partition is removed, the gases will mix without a change in enthalpy. Entropy, however, increases as the gases mix in this spontaneous process and acts as the driving force.

Departamento de Biología Molecular,
Universidad Autónoma de Madrid, Madrid, Spain

Keywords

Acidity · Atmosphere · Ionic strength · Life ·
Molecular ecology · Oceans · Pressure ·
Radiation · Redox conditions · Temperature

Synonyms

[Ecosystem](#); [Habitat](#)

Definition

Natural environment refers to the collection of objects both living and inanimate as well as the fluid, gaseous, or solid media that together make up a ► [habitat](#). The term includes soil, the subsurface, the atmosphere, the oceans and smaller bodies of water, and the interiors of plants and animals. The description of an environment requires definitions of its physical and chemical characteristics – temperature and pressure, acidity, redox conditions, radiation, etc.

Overview

The ensemble of biological communities and their surroundings constitutes an

► [“ecosystem,”](#) and the science that studies these ecosystems is known as Ecology. From a microbiological point of view, “environmental microbiology” studies the microbial processes that take place in the soil, water, food, depuration systems, etc., and “microbial ecology” describes qualitatively and quantitatively the ► [microorganisms](#) that occupy a specific ecological niche and the activities that take place within it. Culture-independent molecular biology techniques, such as in situ hybridization with fluorescent probes (FISH) or those based on PCR- denaturing gradient gel electrophoresis or the creation of genetic libraries, have given rise to “molecular microbial ecology” allowing great steps to be made in the understanding of microbial communities that live in specific habitats that would have been impossible with traditional microbiological research techniques.

Microorganisms occupy extraordinarily diverse habitats needing only liquid water to develop. They not only thrive in soils and water (fresh or marine) with “normal” physical/chemical conditions but have also adapted to ► [extreme environments](#): low and high temperatures and pHs, high salt concentrations, high pressure, etc. Furthermore, given the diminutive size of microorganisms, microniches or microenvironments can exist in conditions, which may differ greatly from those of the general environment, where they are contained. This is especially important in sediments and subsurfaces where the semisolid structure of the substrate allows microniches, whose properties may vary dramatically to coexist in proximity. Environmental conditions are very important in astrobiology because they can determine the habitability of a given planet or planetary body.

Definition

EnVision is the fifth medium-class mission in the ESA's Cosmic Vision program (Space science for Europe 2005) in collaboration with NASA. The Venus orbiter, scheduled for launch in the early 2030s, aims to provide a holistic view of the planet from its core to upper atmosphere and determine how and why Venus and Earth evolved so differently (Ghail et al. 2017; EnVision ESA Assessment Study Report, ESA/SCI 2021). EnVision investigations conducted over six cycles (a sidereal Venus day of 243 Earth days) will provide a leap in our understanding of the history, activity, and climate of our planetary neighbor. (Credit: NASA /ESA /JAXA/ISAS /DARTS /VR2Planets).

History

Venus has been a planet of fascination for centuries, and the object of many space “firsts.” The highly successful early series of Soviet Venera, VeGa, and US Pioneer Venus missions in 1970–1980s revealed an inhospitable world with crushing pressure and furnace-like temperatures on the surface and a corrosive atmosphere with rich exotic chemistry (Hunten et al. 1983). Surface imaging by synthetic aperture radars (SARs) on Venera-15, Venera-16, and NASA's Magellan in 1980–1990s unveiled an alien geology and evolution of the planet (Bougher et al. 1997). In 2000s, ESA's Venus Express and JAXA's Akatsuki missions focused mainly on the atmospheric and plasma investigations (Bezard et al. 2020). Nonetheless, some enigmatic results from Venus Express provided hints of current volcanic activity including a tenfold change in mesospheric sulfur dioxide abundance (Marcq et al. 2013), anomalously dark lavas around volcanoes (Smrekar et al. 2010), and transient hot spots on

EnVision, Fig. a

the surface (Shalygin et al. 2015). To pursue these intriguing discoveries, the EnVision concept was developed to bring Venus geology investigations up to date with twenty-first century SAR capabilities complemented by atmospheric, subsurface, and interior investigations heavily informed by Earth observation heritage.

Overview

Venus exploration offers unique opportunities to answer fundamental questions about the evolution of terrestrial planets and their habitability from within our own solar system. Many significant questions remain about the current state of Venus, suggesting major gaps in our understanding of how Venus's evolutionary pathway diverged from Earth's (Way and Del Genio 2020; Weller and Kiefer 2020). Comparing the interior, surface, and atmospheric evolution of Earth and Venus is essential to understanding what processes have shaped our planet, and is particularly relevant in an era where we expect thousands of terrestrial exoplanets to be discovered (Schiels 2018; Kane et al. 2019).

EnVision Science Questions and Objectives

Venus is Earth's closest sibling geologically and has likely remained active into the present era but does not exhibit Earth-like plate tectonics.

Lacking liquid water to sequester atmospheric CO₂ into carbonate rocks and with few other sinks for volcanically emitted volatiles, Venus is left with its present massive atmosphere. Perched at the inner edge of the habitable zone and having drastically different conditions, Venus provides a natural laboratory for understanding the evolution of terrestrial planets and conditions for life. EnVision will address the following objectives within three major science topics (EnVision ESA Assessment Study Report, ESA/SCI 2021).

1. **History:** *How have the surface and interior of Venus evolved?*
 - Determine the styles of volcanic processes which have occurred on Venus, studying the sources, emplacement styles, magma properties, and relative ages of different volcanic flows.
 - Determine the styles of tectonic deformation that have operated on Venus by studying their surface expression and gravity signatures, and determining their role in planetary heat loss.
 - Characterize surface modification processes such as impact crater modification, low emissivity/radar bright highlands, to improve our understanding of Venus geochronology.
 - Constrain Venus' internal structure, through measurements of gravity field and tidal response, to constrain the properties and

thicknesses of Venus' crust, mantle, and core.

2. **Activity:** *How geologically active is Venus?*

- Constrain the nature and occurrence of recent volcanism on Venus, how processes compare with Earth and other terrestrial planets, characterizing its morphological, thermal, and volatile signatures.
- Study landscape evolution on Venus, such as gravity-driven mass-movements erosion and deposition, and active chemical weathering on time scales of months to years.

3. **Climate:** *How are Venus' atmosphere & climate shaped by geological processes?*

- Explore the role of geological activity, through volcanism and surface-atmosphere chemical reactions, in sustaining the volatile and cloud content of the atmosphere, and climate evolution.
- Study transport of geophysically meaningful volatile species through the atmosphere and clouds of Venus, through measurements below, within, and above the cloud layer.

Scientific strategy and payload. EnVision will synergistically exploit imagery, polarimetry, radiometry, and spectroscopy of the surface coupled with subsurface sounding and gravity mapping, and complemented by tracing key volatile species by spectroscopy and radio-occultation techniques (EnVision ESA Assessment Study Report, ESA/SCI 2021).

EnVision will investigate Venus from its interior to the atmosphere by a suite of five science instruments. A dual polarization S-band **Synthetic Aperture Radar (VenSAR)** designed and built by NASA's JPL will work at 9.5 cm to image pre-selected regions of interest at 30 and 10 meters/pixel resolution, which is key to understanding geological processes from the local to global scale. Topographic information at 300 m spatial and 20 m vertical resolution derived from stereo imaging will be complemented by a global network of altimetry measurements with a vertical resolution of 2.5 m enabling the quantitative analysis of geological processes. Surface properties such as roughness will be derived from active

imaging and passive radiometry in both HH and HV polarizations, which also permits the detection of surface temperature anomalies. Repeated observations and comparisons with Magellan imagery allow for the detection of changes over periods of months, years, and decades. A **Subsurface Sounder (SRS)** procured by University of Trento, Italy, will work at frequency of 9 MHz and will for the first time characterize the vertical structure and stratigraphy of geological units down to ~1 km depth with ~20 m vertical resolution. It will provide information on the surface roughness, composition, and dielectric permittivity at wavelengths longer than those of VenSAR. SRS will also deliver low-resolution surface altimetry. **VenSpec-M spectrometer** (IPF-DLR, Germany) will perform almost global mapping of the surface emissivity in six wavelength bands using six narrow bands in the range from 0.86 to 1.18 μm to constrain surface mineralogy, informing evolutionary scenarios, and undertake a comprehensive search for surface changes and volcanic activity. **VenSpec-H** (BIRA-IASB, Belgium) will use extremely high-resolution infrared spectroscopy to quantify volcanogenic species SO_2 , H_2O , and HDO below and above the clouds, characterizing gas exchanges from the surface and within the atmosphere and searching for sources such as volcanic plumes. It will measure variations of mesospheric species and link them to tropospheric composition and volcanism. **VenSpec-U ultraviolet spectrometer** (LATMOS, France) will monitor minor sulfur-bearing species (mainly SO and SO_2) and investigate the complex and highly variable upper atmosphere and its relationship with the troposphere. A **Radio Science Experiment (RSE)** (LPG, France) will use the spacecraft communications system to map the gravity field with a spatial resolution of ~250 km to better constrain the crustal and lithospheric structure variations and calculate the tidal Love number k_2 with an accuracy of 0.01, sufficient to constrain the distribution of internal mass as well as size and state of the core. The experiment will also probe the structure and composition of the middle atmosphere and the cloud layer and structure of the ionosphere in radio occultations. The synergistic and holistic

EnVision, Fig. 1 EnVision's multi-messenger observation strategy

way in which the payload instruments collaborate to investigate processes at different altitudes, depths, and spatial scales is graphically illustrated in Fig. 1.

Spacecraft and mission design. EnVision will be a three-axis stabilized orbiter approximately 2 m*2 m*3 m in size in stowed configuration with a launch dry mass of about 1350 kg and power consumption of 2.8 kW. EnVision will operate at Venus in a low quasi-polar orbit at 220–540 km altitude and orbital period of ~92 min. EnVision will downlink 210 Tbits of science data using a Ka-/X-band communication system with a 2.5 m diameter fixed high-gain antenna. The spacecraft will be launched by Ariane 6.2 from ESA's spaceport Kourou in 2032 arriving at Venus after a 15-month cruise. Science orbit will be achieved by about 500 days of aerobraking in the Venus upper atmosphere.

The nominal science mission will last for 6 Venus sidereal days (4 Earth years).

EnVision is the ESA-led mission with significant NASA contribution through the provision of VenSAR instrument building on JPL's years of experience with planetary radar. EnVision therefore benefits from decades of scientific and technical heritage from both ESA Venus Express and NASA Magellan missions, as well as from many other missions including Mars Express, Cassini, and Sentinel-1. EnVision will adopt an open data policy, with data publicly released immediately after validation and verification.

Definition

An enzyme is a biological ► **catalyst** necessary for metabolic reactions to occur at an adequate rate under mild conditions of pH and temperature, typically consisting largely or entirely of protein, though catalytic RNA molecules are also known.

History

Enzyme catalysis was discovered by Lazzaro Spallanzani in the eighteenth century as an observation that the digestion of food in the animal stomach was chemical rather than a purely mechanical process of grinding. Subsequent advances in the nineteenth century came primarily from studies of digestion and of the action of yeast in fermentation. Until the early twentieth century, the usual word for enzyme was *ferment*, now entirely superseded by *enzyme*, a name that also referred originally to yeast, as it was coined by Wilhelm Kühne from Greek words meaning “in yeast.” When the last printed version of *Enzyme Nomenclature* was published in 1992, about 3200 distinct enzyme activities were recognized, but the current number is about 6500, and the number of distinct proteins known to be enzymes is very much larger.

Overview

All metabolic reactions are catalyzed by specific molecules called *enzymes*. Even reactions that proceed spontaneously and rapidly, such as the hydration of CO₂, are normally catalyzed in physiological systems. Before the discovery of catalytic RNA molecules (sometimes called ribozymes), all enzymes were believed to consist mainly or entirely of protein molecules, typically with more than 100 ► **amino acid** residues in each

subunit. It is now widely accepted that catalytic RNA satisfies the definition of an enzyme, and the ► **ribosome** is a fundamental example of catalytic RNA (Steitz and Moore 2003). Biological catalysts include metabolites that participate in cycles of reactions, such as citrate, regenerated in each turn of the tricarboxylate (Krebs) cycle, but also many other metabolites. These are certainly catalysts, but they are not conventionally regarded as enzymes; however, from the point of view of astrobiology, they probably should be regarded as enzymes because at the origin of life, there must have been catalysts produced by the first organisms that were neither protein nor RNA, but much simpler molecules.

Although the effectiveness of enzymes as efficient catalysts is normally emphasized, their fundamental property is *specificity* because without specificity, there could be no organization or regulation of metabolic processes. Most enzymes catalyze just one or a small number of reactions and are largely or completely inactive in others that appear quite similar. Bacterial glucokinase, for example, catalyzes the phosphorylation of glucose by ATP, but does not catalyze the phosphorylation of a hexose as similar as mannose. Even relatively unspecific enzymes, mostly involved in catabolic processes such as digestion, are highly specific by the standards of inorganic catalysts. Another property exhibited by all enzymes is *saturation*: although the rate of reaction may be proportional to the concentration of each reactant at low concentrations, it never increases indefinitely with increases in concentration, the rate v typically depending on the substrate concentration a according to the *Michaelis-Menten equation*, $v = Va/(K_m + a)$, in which V , the *limiting rate*, and K_m , the *Michaelis constant*, are constants. In vivo, however, enzymes typically operate in or close to the proportional zone, in other words at substrate concentrations similar to or smaller than K_m . Certain enzymes, known as *regulatory enzymes*, are inhibited or activated by molecules structurally different from their substrates or products, which are called *effectors*, or display special kinetic laws that enable them to respond with high sensitivity to changes in conditions. The part of an enzyme

where catalysis occurs is called the *active site*, and if a different site exists for binding effectors, it is called an *allosteric site*.

Enzymes are grouped in *Enzyme Nomenclature* into six classes, of which three (oxidoreductases, transferases, and hydrolases) catalyze group-transfer reactions and three (lyases, isomerases, and ligases) catalyze other types of reaction. This is a classification of reactions catalyzed, not a classification of proteins catalyzing them. The number of known proteins acting as enzymes is very much larger than the number of known activities (because the proteins catalyzing any given reaction in different organisms are nearly always different), and the amount of variation in structure among the known cases suggests that the total number is huge. In most of the known cases, the proteins are similar enough to be clearly homologous, but some exceptions, exemplified by superoxide dismutase, are known. Even within a single species, it is common to find multiple proteins, known as *isoenzymes*, catalyzing the same reaction, often with distinct regulatory properties.

Enzymology, History of

Stéphane Tirard

Centre François Viète d'Histoire des Sciences et des Techniques EA 1161, Faculté des Sciences et des Techniques de Nantes, Nantes, France

Definition

In 1833, the French biologists A. Payen (1795–1871) and J. F. Persoz (1805–1868) isolated a malt-soluble ferment able to digest the amide and called it diastase. In 1878, the German physiologist Wilhelm Kühne (1837–1900) named the contents of this digestive juice as enzyme. During the second part of the nineteenth century, there was an active debate between Louis Pasteur (1822–1895) and Justus Freiherr von Liebig (1803–1873) about the cause of fermentation. Pasteur argued that fermentation is a process of microscopic living entities, like yeast, and Liebig argued that fermentation is a spontaneous decomposition of matter.

In 1897, the German chemistry Edüard Buchner (1860–1917) made an *in vitro* fermentation of sugars in an acellular fraction of yeast. Some authors said that this result probably constituted the beginning of biochemistry science. A few years later, in 1903, the French-Russian physical chemist Victor Henry (1872–1940) stated that all enzymes are proteins.

The 1920s have witnessed important developments of enzymology with the purification and the crystallization of numerous enzymes (urease, pepsin, trypsin, etc.) and the study of the enzymatic kinetic.

EPOXI Mission

William M. Irvine
University of Massachusetts, Amherst, MA, USA

Definition

EPOXI was an extension of the NASA Deep Impact mission (► [Deep Impact](#)) with two goals: to observe extrasolar planets using the transit method and to study comet 103P/Hartley 2 using the same instruments used for the Deep Impact observations of comet 9P/Tempel 1. Several transiting planets were observed, and Earth was also observed, in an effort to see what characteristics of Earth-like planets might be most easily measured remotely. The closest approach to comet 103P/Hartley 2 occurred on November 4, 2010. The name EPOXI is a hybrid of EPOCH (Extrasolar Planet Observation and CHaracterization Investigation) and DIXI (Deep Impact eXtended Investigation). The EPOXI Mission web page maintained by NASA includes status reports on the various activities undertaken (<http://epoxi.umd.edu/1mission/status.shtml>).

The team working with EPOXI lost communication to the spacecraft sometime between August 11 and 14, 2013. On Monday, September 16, 2013, after considerable effort transmitting low-level hardware commands, EPOXI team determined that there were no other plausible scenarios under which they could recover command

and control of the spacecraft. They recommended that NASA declares the mission lost. That declaration was announced by NASA on Thursday, September 19, 2013.

Equation of State

Tristan Guillot
Observatoire de la Côte d'Azur, Université de
Nice-Sophia Antipolis, Nice, France

Keywords

Density · Pressure · Temperature ·
Thermodynamics

Definition

An equation of state is a relation (or by extension a series of relations) between thermodynamic state variables characterizing matter in a given state, for instance, in a celestial body. It describes how a macroscopic entity is affected by external changes (e.g., changes in temperature, pressure, volume, etc.). When modeling stars and planets, equations of state are used in particular to calculate density as a function of pressure and temperature, the phases (e.g., gaseous, liquid, solid, etc.) of the materials considered, and how temperature

changes with pressure during macroscopic motions.

Overview

The first and most widely known equation of state is the so-called ideal gas law. It links the pressure P , volume V , absolute temperature T , and number of particles N in a gas composed of nonrelativistic, noninteracting mass particles through the relation $PV = NkT$, where $k = 1.38065034 \times 10^{23} \text{ J K}^{-1}$ is Boltzmann's constant. Equations of state of arbitrary complexity can be calculated for elements that undergo a phase transition (i.e., become gaseous, liquid, or solid), for mixtures, for photons, for charged particles, in the presence of magnetic fields, etc. Among other things, equations of state are crucial to model atmospheric structures: when a parcel of air (or fluid) is transformed (e.g., by its motion) without losing heat (i.e., *adiabatically*), it conserves its ► [entropy](#). Entropy is a thermodynamic state variable and, as such, it also obeys an equation of state relation that links it to the other thermodynamic state variables of the problem (e.g., temperature, pressure). Using its conservation, one can therefore calculate the rate of change of temperature with pressure in such a transformation. In atmospheres that are thick enough for convection to occur nearly adiabatically, the temperature profile is mostly set by the temperature of the photosphere (the level at which most of the photons can escape freely to space) and by the equation of state of the atmospheric mixture.

Equations of state are also at the heart of our knowledge of planetary and stellar interiors. They describe how matter is affected by the extreme conditions that occur there. With a pressure of about 360 GPa (about 3.6 million times the atmospheric pressure at sea level on Earth) and a temperature of about 7000 K, the iron which forms most of the core at the center of the Earth is believed to be in solid form. However, the equation of state of iron tells us that at conditions relevant slightly higher up in the Earth, it should be liquid, therefore forming the so-called liquid

outer core. In giant planets such as Jupiter and Saturn, the equation of state of hydrogen indicates that this element ionizes from a molecular state, H_2 , to a conducting state called metallic hydrogen at pressures of about 150 GPa and temperatures of 10,000 K or less.

[Autumnal point](#); [Vernal point](#)

Definition

The equinox is one or the other of the two points on the celestial sphere where the equatorial plane intersects the ► [ecliptic](#) plane. When the Sun is at one of these points, daytime and nighttime have the same duration everywhere on Earth. The term equinox is also used for the date and time corresponding to those two positions of the Sun, which mark the beginning of spring (vernal equinox) and the beginning of fall (autumnal equinox).

ERA

Gerda Horneck
DLR German Aerospace Center, Institute of
Aerospace Medicine, Radiation Biology, Köln,
Germany

Definition

The Exobiology Radiation Assembly (ERA) is a facility to expose various chemical and biological objects to the conditions of outer space, such as space vacuum, solar extraterrestrial radiation, and cosmic rays.

Overview

ERA was mounted on the sun-pointing cold plate of ESA's European Retrievable Carrier (► [EURECA](#)), which was launched to Low Earth Orbit (LEO) on July 31, 1992, and remained there until August 7, 1993 (Innocenti and Mesland 1995). ERA consisted of an exposure tray (Fig. 1) and a lid accommodating the following experiments:

- Exobiological unit that studied the action of solar UV radiation and/or space vacuum on the survival and genetic changes of invertebrates, ► [microorganisms](#), viruses, and DNA and the role of chemical and physical protection mechanisms (Horneck et al. 1995).
- Space biochemistry that elucidated dehydration and photochemical reactions in cellular, subcellular, and molecular systems under outer space conditions (Dose et al. 1995).
- Effects of solar UV on yeast cells
- Photoprocessing of grain mantle analogues that studied photolytical processes during chemical evolution of interstellar grains (Greenberg 2000)

Beneath the tray was another compartment accommodating the following experiment:

ERA, Fig. 1 Tray of the exposure facility ERA with sample carriers and optical filters during assembly. (Credit ESA, from Horneck et al. 2010)

- Free Flyer ► [Biostack](#) that studied the biological responses of different systems to the structured components of cosmic radiation, i.e., ► [HZE particles](#) (cosmic rays consisting of energetic nuclei with atomic number 3 or greater) and nuclear disintegration events (Reitz et al. 1995; Horneck 2007; Horneck et al. 2010).

Eros Asteroid

Gerhard Hahn
Asteroids and Comets, DLR, Institute of
Planetary Research, Berlin, Germany

Synonyms

[Asteroid \(433\) Eros](#)

Definition

(433) Eros is the second largest Amor asteroid, of irregular shape measuring $34 \times 11 \times 11$ km and of spectral type S. Its rotation period is 5.27 h, exhibiting large brightness variations caused by the elongated shape. In 2000, NASA's NEAR-Shoemaker mission visited the asteroid, orbiting it for about 1 year, before descending to the surface.

History

(433) Eros was discovered on August 13, 1898, by Gustav Witt in Berlin and almost simultaneously by Auguste Charlois in Nice (see Scholl and Schmadel (2002) for details). It was the first near-Earth asteroid found.

Error Rate

Ester Lázaro
Molecular Evolution Laboratory, Centro de Astrobiología (CSIC-INTA), Madrid, Spain

Definition

In biology, the error rate is the average number of ► [mutations](#) per nucleotide and round of

copy produced during genomic ► [replication](#). For example, an error rate of 10^{-10} in a certain species means that, in average, one in every 10^{10} nucleotides will be misincorporated each time its genome is replicated. The error rate varies by orders of magnitude among species (from 10^{-3} – 10^{-5} in RNA viruses to 10^{-9} – 10^{-12} in cellular organisms). It also can present intraspecific variations, depending on the nature and frequency of change of the selective pressures. The optimal value of the error rate results from the necessity to optimize different conflicting features, such as the generation of genetic diversity, the preservation of genetic information, the minimization of the number of deleterious mutations, and the metabolic costs of systems that increase replication fidelity.

ESA Solar Orbiter Mission

Olivier Witasse
European Space Agency (ESA), European Space Research and Technology Centre (ESTEC), Noordwijk, The Netherlands

Keywords

Sun · Solar wind · Heliophysics · ESA mission

Synonyms

ESA – European Space Agency; NASA

Definition

Solar Orbiter is an ESA-led mission with strong NASA participation which was launched on 10 February 2020 from Cape Canaveral. It carries the most comprehensive payload flown in the inner heliosphere to date, with six remote sensing instruments that image the Sun and its surroundings as well as four in situ instruments for monitoring the solar wind. The mission will address key questions of solar and heliospheric physics pertaining to how the Sun creates and controls the heliosphere, and why solar activity changes with time.

History

The Solar Orbiter mission has its origins in a proposal called “Messenger” that was submitted in 1982 in response to an ESA call for mission ideas. At the meeting “Crossroads for European Solar and Heliospheric Physics” held on Tenerife in March 1998, the heliophysics community recommended to launch an ESA Solar Orbiter as ESA’s next flexible mission, with possible international participation, for launch around 2007. Solar Orbiter was eventually selected and adopted as the first M-class mission of ESA’s Cosmic Vision program in October 2011. The spacecraft was launched on 10 February 2020 on board an Atlas V launcher from Cape Canaveral, completed the in-orbit commissioning in June 2020, and its cruise phase in December 2021, when it started nominal science operations.

Overview

Solar Orbiter is an ESA mission with strong NASA participation dedicated to solar and heliospheric physics.

Solar Orbiter’s elliptic orbit put the spacecraft between 1.2 and 0.28 AU from the Sun. The operational orbit is reached in 2022 by using gravity assist maneuvers at Earth and Venus. Subsequent Venus flybys will increase its inclination with respect to the solar equator, reaching up to 24° at the end of the nominal mission (approximately 7 years after launch) and up to 33.4° in the extended mission phase.

Solar Orbiter aims to make significant breakthroughs in our understanding both of how the inner heliosphere works, and of the effects of solar activity on it. The spacecraft will take a unique combination of measurements: in situ measurements will be used alongside remote sensing close to the Sun to relate these measurements back to their source regions and structures on the Sun’s surface. It will operate both in and out of the ecliptic plane.

Solar Orbiter will study solar energetic particles that may be hazardous to human explorers as well as spacecrafts that operate in the highly variable environment outside of Earth’s magnetosphere. Beyond our own solar system, studying the Sun and the solar wind is also relevant for our understanding of other stellar systems.

The payload includes a combination of four in situ and six remote sensing instruments, with a total mass of 209 kg:

- 1) EPD (energetic particle detector) is an instrument suite comprising different sensors that measures the properties of suprathermal ions and energetic particles in the energy range of a few keV/n to relativistic electrons and high-energy ions.
- 2) MAG (magnetometer) measures the in situ magnetic field.
- 3) The RPW (radio and plasma waves) instrument measures magnetic and electric fields, plasma wave spectra and polarization properties, as well as the spacecraft floating potential and radio emissions of solar origin generated in the interplanetary medium.

- 4) SWA (solar wind analyzer) instrument suite measures the ion and electron bulk properties (including density, velocity, and temperature) of the solar wind and its ion composition for key elements.
- 5) EUI (extreme ultraviolet imager) provides images of the solar atmospheric layers above the photosphere, providing an indispensable link between the solar surface and outer corona that ultimately shapes the characteristics of the interplanetary medium. EUI will also provide the first-ever UV images of the Sun from an out-of-ecliptic viewpoint.
- 6) Metis is a coronagraph that simultaneously images the visible and ultraviolet emission of the solar corona and diagnose, with unprecedented temporal coverage and spatial resolution, the structure and dynamics of the full corona.
- 7) PHI (polarimetric and helioseismic imager) provides high-resolution and full-disc measurements of the photospheric vector magnetic field and line-of-sight velocity as well as the continuum intensity in the visible wavelength range. The line-of-sight velocity maps will have the accuracy and stability to allow detailed helioseismic investigations of the solar interior, in particular of the solar convection zone.
- 8) SoloHI (heliospheric imager) images the inner heliosphere over a wide field of view by observing visible photospheric light scattered by electrons in the solar wind emitted by the Sun and interplanetary dust in orbit about the Sun. It will provide unique measurements to pinpoint coronal mass ejections.
- 9) SPICE (spectral imaging of the coronal environment) performs extreme ultraviolet imaging spectroscopy to remotely characterize plasma properties of the Sun's on-disc corona. This will enable matching in situ composition signatures of solar wind streams to their source regions on the Sun's surface.
- 10) STIX (X-ray spectrometer/telescope) provides imaging spectroscopy of solar

thermal and nonthermal X-ray emission. STIX will provide quantitative information on the timing, location, intensity, and spectra of accelerated electrons as well as of high temperature thermal plasmas, mostly associated with flares and/or microflares.

Escape Velocity

Sean N. Raymond

Laboratoire d'Astrophysique de Bordeaux,
CNRS, Université de Bordeaux, Bordeaux,
France

Definition

Escape velocity is the critical velocity above which a body is no longer gravitationally bound to a larger mass. This is important for numerous processes: atmospheric molecules escaping from a planet, a planet escaping from its host star, and stars escaping from either mutual orbits or stellar clusters. For a simple

Keplerian potential (where the gravitational force is proportional to the central mass and inversely proportional to the distance squared), the escape speed is given by

$$v_{\text{esc}} = \sqrt{2G \frac{M}{R}}$$

where G is the gravitational constant, M is the central mass, and R is the distance from the central mass.

Acronyms

Echelle Spectrograph for Rocky Exoplanets and
Stable Spectroscopy Observations

Definition

ESPRESSO is a high-resolution spectrograph on the Very-Large Telescope (VLT) at ESO's Paranal Observatory, Chile. It operates in the optical wavelength range from 380 to 780 nm and delivers spectral resolution up to $R = \lambda / \Delta\lambda = 200\,000$. ESPRESSO is the first instrument of the VLT able to combine incoherently the light from the four 8-m telescopes and turn the VLT into a 16-m equivalent telescope. The speciality of ESPRESSO is, on the example of its predecessor HARPS, the extreme precision that is required for the search and characterization of low-mass exoplanets, the study of fundamental physical constants and cosmology.

Ester

Henderson James Cleaves II
Earth-Life Science Institute (ELSI), Tokyo
Institute of Technology, Tokyo, Japan
Blue Marble Space Institute of Science,
Washington, DC, USA
Georgia Institute of Technology, Center for
Chemical Evolution, Atlanta, GA, USA

Definition

In chemistry, esters are compounds derived by condensation of an oxoacid (one containing an oxo group, $X = O$, e.g., phosphoric acid ($O=P(OH)_3$) or a carboxylic acid ($RCOOH$)) with an alcohol. Many biological lipids are fatty acid esters of glycerol derivatives. Phosphoesters form the backbone of DNA molecules. Polyesters such as poly-hydroxy butyrate are important energy storage molecules in some microbes. Cyclic esters formed from carboxylic acid and alcohol functional groups are called lactones.

Esters contain a carbonyl functionality, but unlike amides, esters are structurally flexible because there is a low energetic barrier to rotation about the $X(=O)-O-C$ bond. Esters thus tend to be more volatile (i.e., have a lower boiling point, particularly with low molecular weight esters) than the corresponding amides. Their carbonyl group can serve as a hydrogen bond acceptor, and this ability to engage in hydrogen bonding renders them somewhat water soluble. The inability of the linking ester oxygen atom to engage in hydrogen bonding with another ester group, unlike the protonated nitrogen atom in an amide or a protonated carboxylic acid, also results in their greater structural flexibility and volatility, but renders them unable to form the hydrogen-bonded structural motifs such as α -helices and β -sheets that polyamides can.

Esters can react at one of two locations of their molecular structure. The carbonyl group is weakly electrophilic and is attacked by strong nucleophiles (amines, alkoxides, etc.). The C–H bonds of the carbon atoms adjacent to the carbonyl group are weakly acidic but can be deprotonated by

strong bases and can thus serve as nucleophiles. Esters undergo both acid- and base-catalyzed hydrolysis. Under basic conditions, hydroxide acts as a nucleophile, while an alkoxide is the leaving group. This reaction is known as saponification. Esters may also be cleaved by amines such as ammonia and primary or secondary amines to give amides, in a process known as aminolysis or amidation.

Eta-Earth

Nader Haghighipour
Institute for Astronomy, University of Hawaii-
Manoa, Honolulu, HI, USA

Definition

The term eta-Earth (also written as η_E) is defined as the mean number per star of rocky planets with between 1 and 1.5–2 Earth-radii that reside in the optimistic habitable zone (HZ) of their host star. Eta-Earth enters one formulation of the ► [Drake equation](#), which endeavors to estimate the occurrence of intelligent life in the Galaxy; at the present time, it is usually calculated separately for each stellar spectral type. Thus, eta-Earth represents the occurrence rate of rocky planets in the optimistic HZ of different stars.

The references present some values for eta Earth based on different statistical analyses of the data from the Kepler space telescope.

Ethane

Kensei Kobayashi
Department of Chemistry, Yokohama National University, Yokohama, Japan

Chemical Formula

C_2H_6

Definition

Ethane, C_2H_6 , is a saturated hydrocarbon having two carbon atoms, whose molecular weight is 30.07. It is a colorless, odorless gas at ambient temperature and pressure. It is a component of natural gas and can be obtained during petroleum refining. Its melting point is $-182.9\text{ }^{\circ}\text{C}$, and its boiling point is $-88.5\text{ }^{\circ}\text{C}$. When a hydrogen atom is substituted with the other atom or group, the ethane moiety (i.e., a part or functional group of a molecule) is called an ethyl group. Acetylene (ethyne, C_2H_2) and ethylene (ethene, C_2H_4) are two other aliphatic hydrocarbons with two carbon atoms. Ethane has been detected in the atmosphere of the outer planets (Jupiter, Saturn, Uranus, and Neptune) as well as in a number of comets (Dello Russo et al. 2001), but it has not been identified as

an interstellar molecule until now (September 2019). Ethane is also found in the atmosphere of Titan. Cassini spacecraft found hydrocarbon lakes on the surface of Titan, and ethane was detected in it with its Visible and Infrared Mapping Spectrometer (VIMS) in 2008 (Brown et al. 2008). The surface temperature of Titan is about $-179\text{ }^{\circ}\text{C}$, so ethane can exist as liquid.

Ethanol, Fig. 1 Rotational isomers of ethanol

Ethanol

Kensei Kobayashi

Yokohama National University, Yokohama, Japan

Synonyms

[Ethyl alcohol](#)

Definition

Ethanol is an organic compound belonging to the group of ► [alcohols](#) whose structural formula is $\text{C}_2\text{H}_5\text{OH}$. It is a constituent of alcoholic beverages. Ethanol is a colorless, volatile, and flammable liquid. Its melting and boiling points are -114.3°C and 78.4°C , respectively. It is made from sugar by fermentation, and it is metabolized in vivo to carbon dioxide via acetaldehyde and acetic acid. Ethanol has rotational isomers, and they are referred to as trans-ethanol and gauche-ethanol (Fig. 1). In 1975, trans-ethanol was identified as an interstellar molecule, while gauche-ethanol was detected in 1996. Ethanol condenses with carboxylic acids to form esters, and it condenses with itself to form diethyl ether.

Ether

Henderson James Cleaves II
Earth-Life Science Institute (ELSI), Tokyo
Institute of Technology, Tokyo, Japan
Blue Marble Space Institute of Science,
Washington, DC, USA
Center for Chemical Evolution, Georgia Institute
of Technology, Atlanta, GA, USA

Definition

Ethers are a class of organic compounds containing an ether group (R-O-R) – an oxygen atom connecting two alkyl or aryl groups. A typical example is diethyl ether, commonly referred to simply as “ether” (CH₃-CH₂-O-CH₂-CH₃). Polyethers are compounds with more than one ether group. Low- to medium-range molecular weight polyethers with a hydroxyl end group are termed glycols. The crown ethers are examples of low-molecular weight cyclic polyethers. Other common cyclic ethers include the furans (five-membered rings) and epoxides (three-membered rings).

Ethers cannot form intermolecular hydrogen bonds between each other, resulting in relatively low boiling points compared to their parent alcohols. The difference in the boiling points of ethers and their parent alcohols becomes less significant as the carbon chains become longer, as van der Waals interactions between the extended carbon chains come to dominate intermolecular interaction.

Ethers in general are of low chemical reactivity, and indeed in many extremophilic organisms, the cell membranes contain glycerol ethers rather than glycerol esters.

Ethyl Cyanide (CH₃CH₂CN)

William M. Irvine
University of Massachusetts, Amherst, MA, USA

Synonyms

CH₃CH₂CN; [Cyanoethane](#); [Propanenitrile](#) (IUPAC name); [Propionitrile](#)

Definition

Under standard laboratory conditions, ethyl cyanide is a clear liquid with a sweet odor. It is commonly found in the gas phase in interstellar molecular clouds, specifically in “hot cores” (the regions where massive stars are forming), and has more recently been located in regions of low-mass star formation (hot corinos). Ethyl cyanide has a rich rotational spectrum that is observed by radio astronomers in the millimeter wavelength region. In addition to transitions in the ground vibrational state, rotational lines in low-lying vibrational states have been detected. All three 13-carbon isotopic species have been detected in hot cores.

History

The first astronomical detection was made by Johnson et al. (1977); subsequently it has been found in most spectral surveys of hot cores (e.g., Nummelin et al. 2000; Daly et al. 2013).

Ethyl Formate

William M. Irvine
University of Massachusetts, Amherst, MA, USA

Synonyms

[C₂H₅OCHO](#); [Ethyl methanoate](#)

Definition

Ethyl formate is among the largest organic molecules unambiguously detected by radio astronomers in the interstellar medium. It is also called ethyl methanoate. Ethyl formate is partly responsible for the flavor of raspberries, and it has the characteristic odor of rum.

History

The *trans* conformer of ethyl formate was detected in the Galactic Center molecular cloud Sagittarius B2(N) by Belloche et al. (2009), who suggest that it may be produced by surface reactions on interstellar dust grains, perhaps involving precursors such

as methyl formate and ethanol (for the definition of conformers, see ► [isomer](#)). More recently, the *gauche* conformer has also been detected, in a line survey of the Orion molecular cloud (Tercero et al. 2013). Ethyl formate is the second formate, after ► [methyl formate](#), to be detected in the ► [interstellar medium](#). Its isomer methyl acetate (CH₃COOCH₃) has also been recently detected in a molecular cloud in the Milky Way.

Ethylene Glycol (HOCH₂CH₂OH)

Didier Despois¹ and Audrey Coutens²

¹Laboratoire d'Astrophysique de Bordeaux, Université de Bordeaux, Pessac, France

²Institut de Recherche en Astrophysique et Planétologie, Université de Toulouse, Toulouse, France

Synonyms

(CH₂OH)₂; 1,2-Ethanediol; Glycol;
HOCH₂CH₂OH

Chemical Formula

HOCH₂CH₂OH; (CH₂OH)₂

Definition

Ethylene glycol [IUPAC name 1,2-ethanediol] is the simplest dialcohol (or diol). A (toxic) liquid under the standard pressure from 197 °C down to −12 °C, its mixture (70–30%) with water remains liquid down to −51 °C, which explains its use as antifreeze. It is currently produced by reaction of ► [ethylene oxide](#) (oxirane, C₂H₄O) with water. Ethylene glycol has been found in the interstellar medium and in ► [comets](#).

History

Detection of ethylene glycol in the interstellar medium was rather difficult; it was performed for the first time by Hollis et al. (2002) toward the galactic center (► [SgrB2](#)). This contrasts with the relative strength of the lines in comet C/1995 O1 (► [Hale-Bopp](#)), where this molecule was identified in archive spectra as soon as the line frequencies were available (Crovisier et al. 2004). Since then, ethylene glycol has been found in several ► [comets](#) (e.g., Biver et al. 2014, 2021, Goesmann et al. 2015) and star-forming regions of different masses (e.g., Fuente et al. 2014, Maury et al. 2014, and Brouillet et al. 2015). Several conformers of ethylene glycol exist (Hollis et al. 2002), and the astronomical detections prior to 2012 referred to the lowest energy conformer (aGg'). A second conformer (gGg') was first tentatively identified towards ► [IRAS 16293–2422](#) by Jørgensen et al. (2012) and later confirmed by Jørgensen et al. (2016).

Ethylene Oxide (C₂H₄O)

William M. Irvine

Department of Astronomy, University of
Massachusetts, Amherst, MA, USA

Synonyms

C₂H₄O; Oxirane

Definition

Under laboratory conditions, ethylene oxide is a colorless, flammable gas.

History

Ethylene oxide was isolated in 1859 by the French chemist C.A. Wurtz. It subsequently became commercially important as a precursor to ethylene glycol, and it was used during World War I in the production of mustard gas. The astronomical detection was carried out after a failed search for its derivative, oxiranecarbonitrile (C₃H₃NO), which had been suggested as a possible precursor to glycolaldehyde phosphate and hence to sugar phosphates (Dickens et al. 1996). Ethylene oxide (IUPAC name oxirane) is one of only a handful of cyclic molecules that have been found in the interstellar medium, all of which except benzene and benzene derivatives involve three-membered rings. It was detected by radio astronomers by observing pure rotational transitions at millimeter wavelengths in the Galactic Center ► [hot core SgrB2\(N\)](#) (Dickens et al. 1997). Ethylene oxide is isomeric with ► [acetaldehyde](#) (CH₃CHO) and vinyl alcohol (CH₂CHOH), both of which are also observed in the interstellar medium. NASA has used ethylene oxide for sterilization of spacecraft as part of its ► [planetary protection](#) program.

Ethynyl Radical (C_2H)

William M. Irvine
University of Massachusetts, Amherst, MA, USA

Synonyms

C_2H

Definition

This triatomic ► [radical](#) plays an important role in the gas phase chemistry of interstellar

► [molecular clouds](#), since it provides a link in the chemistry of acetylene and higher-order polyacetylenes, the presence of the latter being deduced from observations of the corresponding nitriles (► [cyanopolylyne](#)). Both carbon-13 and deuterated isotopic variants of C_2H are observed in ► [molecular clouds](#).

History

The fundamental pure rotational transition ($N = 1 - 0$) of C_2H at a frequency of 87 GHz was observed astronomically before corresponding laboratory measurements were available, with the identification resting on the pattern of the four detected hyperfine components (Tucker et al. 1974).

Definition

Eukarya is one of the three domains of life distinguished from ► [Bacteria](#) and ► [Archaea](#) at the morphological and molecular levels. All members of the Eukarya have a nucleus and are further distinguished from *Bacteria* and *Archaea* by a complex cellular organization with ultrastructural features including but not limited to nuclear pores, endoplasmic reticulum, 9 + 2 flagellar apparatus, mitotic spindle formation, acidified vacuoles, Golgi apparatus, multiple linear chromosomes, eukaryotic telomeres, and cellular processes that typically include mitosis, meiotic sex, endocytosis, and mitochondrial respiration. They are also differentiated from the other two domains by the presence of specific genes and proteins (e.g., tubulins, actin, dyneins, centrin, myosin, calmodulin, and ubiquitin).

Overview

Members of the domain Eukarya include both unicellular and multicellular representatives from the ~1-μm ocean-dwelling “picoplanktonic” alga *Ostreococcus* to the blue whale (~34 m) – a difference in size of over 7 orders of magnitude. Animals, plants, and

► [fungi](#) all have microbial eukaryotic (protistan) sister groups. Traditional taxonomic classifications of the Eukarya are morphology based and have described ~1.25 million animal species (mostly insects), 297,326 plant species and ~75,000 fungal species, and ~200,000 protistan species (<http://www.eol.org/>). Single-cell and some multicellular protists contribute to the greatest diversity of life on Earth in the domain Eukarya. Beginning in the 1960s, a large portion of this diversity was unveiled with the assistance of technologies including high-powered electron microscopy. Unlike bacteria and archaea, many microbial eukaryotes have ultrastructural features that can help to differentiate the major groups. These ultrastructural features are summarized in below (Patterson 1999).

Ultrastructural features that differentiate major groups of eukaryotes are:

- Shape of mitochondrial cristae (i.e., tubular, elongated, branching, flat, or discoidal)
- Presence or absence of hairs, scales, or other extensions on the flagella
- Organization of the axoneme into the nine-triplet structure of the basal bodies
- Basal body length and orientation association with other organelles
- Microtubule and rootlet structures arising from the basal bodies
- Source and deployment of microtubular or other cytoskeletal arrays within the cell
- Presence and nature of microtubule-organizing centers
- Number, nature, and heterogeneity of nuclei, structures within the nuclear envelope, intranuclear and paranuclear inclusions
- Behavior of the nuclear envelope during mitosis
- Behavior of the mitotic spindle
- For chloroplast-containing cells: number of bounding membranes, thylakoids per lamella, and the presence and nature of contained (e.g., stigma) or associated (e.g., nucleomorph) organelles
- Identity and nature of other membrane-bound organelles in the cell

Based on these ultrastructural features, Patterson (1999) defined 71 groups of protists but identified an additional 200 with no clear ultrastructural identity. While ultrastructure has its virtues in the eukaryotic domain, molecular approaches quickly superseded morphological ones in accelerating our ability to delineate species and higher-order taxa of eukaryotes. After Woese and Fox's (1977) seminal work on applying ribosomal RNA-based strategy for inferring the relationships between the major branches of the tree of life, this approach quickly became the gold standard in molecular systematics studies in the 1980s and 1990s across all domains of life. In 1990, Woese et al. (1990) formally erected the three domains including the *Bacteria*, *Archaea*, and *Eukarya*. Many studies employing rRNA-based approaches ensued and made important contributions to the placement of eukaryotes into major groups (Sogin 1991).

Despite insights gained in applying molecular metrics to redefining the organization of life, modern taxonomic revisions have been slow to reach textbooks. The animal-plant dichotomy was replaced with the Whittaker five kingdoms recognizing *Monera*, *Animalia*, *Plantae*, *Fungi*, and *Protista*, but the transition to the three-domain classification has been a gradual one at best. Another holdfast has been the prokaryote-eukaryote dichotomy. Pace (2006) pointed out the need to recognize the value of the three-domain system in doing away with the artificial lumping of bacteria and archaea via the term "prokaryote." While ribosomal RNA approaches failed to unveil higher-order relationships between the three domains, amino acid-based analyses using vacuolar H⁺-ATPases showed that *Archaea* are more closely related to *Eukarya* than they are to *Bacteria* (Gogarten et al. 1989), further obfuscating the prokaryote-eukaryote division.

While important in establishing lower-level taxonomic relationships, single-gene approaches such as rRNA, tubulin, and others often returned ambiguous relationships between major groups of eukaryotes. The adoption of multigene phylogenetic approaches to inferring relationships between eukaryotes, followed by the use of

genomic and expressed sequence tag (EST) data, ushered in the "phylogenomic" era in eukaryotic phylogeny research. These approaches allowed for the testing of relationships between major lineages of eukaryotes and lead to the adoption of the "supergroup" concept of eukaryotic phylogeny that encompasses a varying number of higher taxonomic groupings than phyla depending on the extent of the supergroup. These include the Opisthokonta, Amoebozoa, Archaeplastida (*Plantae*), Rhizaria, Chromalveolata (chromalveolates, chromists plus alveolates), and the Excavata (Baldauf 2003; Keeling et al. 2005; Simpson and Roger 2004).

More detailed information on these supergroups can be found in the references listed above, but a brief description follows. The Opisthokonta encompass the animal and fungal kingdoms, as well as several groups of protists related to both of these lineages, choanoflagellates and Mesomycetozoea (a group of parasitic protists, many in fishes), branch with the animals, and nucleariids and microsporidia (a group of obligate endoparasites) branch with the *Fungi*. Their name reveals the nature of the synapomorphy or shared derived trait that its members share – a single posterior flagellum. This higher-order relationship between two kingdom-level eukaryotic groups has been known for some time and was first proposed on the basis of morphological characters (Cavalier-Smith 1987), confirmed via single-gene rRNA-based molecular analyses (Wainright et al. 1993) and more recently supported by various phylogenomic investigations (Burki et al. 2007; Hampl et al. 2009; Parfrey et al. 2006).

The Amoebozoa form a second supergroup comprising lobose amoebae, slime molds, as well as some amitochondriate amoebae including pelobionts and entamoebae (sometimes referred to as Archamoebae). Like the terms "alga" and "worm," "amoeba" joins the ranks of ecological concepts as opposed to phylogenetic ones because the term does not refer to a coherent group of organisms that share common ancestry. Amoeboid organisms, organisms that possess pseudopodia or "false feet" that enable the cell to engulf food via phagocytosis, are sprinkled over the tree of life and occur in the Opisthokonta

(i.e., nucleariids), Amoebozoa, Rhizaria (i.e., Foraminifera, Polycystines, Phaeodaria, Acantharea), and Excavata (i.e., Heterolobosea). Amoebozoa include free-living, facultative, and obligate parasites including the genus *Amoeba*, *Acanthamoeba*, and *Entamoeba*. As with the Opisthokonta, Amoebozoa have multicellular representatives including members of the slime molds such as *Dictyostelium*.

The Plantae supergroup, also called the Archaeplastida, includes unicellular and multicellular members such as the land plants, charophytes, chlorophytes, red [algae](#), and glaucophytes. All the members of this group are photosynthetic or contain relict plastids resulting from a primary endosymbiosis with a cyanobacterium. Surprisingly, a recent phylogenomic assessment of this supergroup along with other supergroups including 143 proteins and 48 taxa failed to support the monophyly of the Archaeplastida (Hampel et al. 2009). Beyond systematic errors associated with the analysis, one possible explanation is related to the symptomatic problem of the host nuclear genome being a potential mosaic of genes derived from multiple nuclei (Lane and Archibald 2008).

The Chromalveolata supergroup itself contains higher-order groupings of eukaryotes including the alveolates (i.e., ciliates, apicomplexans, dinoflagellates) and chromists (Stramenopiles – brown algae, diatoms, pelagophytes, labyrinthulids, oomycetes, bicosoecids, opalindids), haptophytes, and cryptomonads. Members of this supergroup are ecologically diverse ranging from free-living to obligately parasitic and heterotrophic, autotrophic, and mixotrophic. The Chromalveolates remains among the most controversial of supergroups and may require more taxon sampling to justify (Hampel et al. 2009).

The Rhizaria consists of unicellular and colony-forming (therefore multicellular) protists that include the geologically significant Radiolaria and Foraminifera that are well preserved in the fossil record, as well as a hodgepodge of other amoeboid and flagellated forms collectively referred to as the Cercozoa. Members of the Radiolaria have been detected in molecular studies targeting picoplankton-sized (<2 μm) cells, as

well as colonies that reach several meters in length. In addition to exhibiting extreme morphological variability, like the Chromalveolates, the supergroup also exhibits varied ecological roles including heterotrophic, autotrophic, and parasitic lifestyles, and many members of the Radiolaria and Foraminifera in particular possess symbiotic algae. Rhizaria is defined solely on the basis of molecular phylogenies and lacks any synapomorphic characters.

The final supergroup is the Excavata (Patterson 1999) that include the Heterolobosea, euglenids, diplomonids, kinetoplastids, jacobids, *Carpodemonas*, diplomonads, retortamonads, trichomonads, hypermastigotes, *Trimastix*, and the oxymonads. Phylogenomic analyses have only recently supported the monophyly of this supergroup (Hampel et al. 2009), which, unlike other supergroups, was primarily conceived on the basis of an ultrastructural feature of a distinctive ventral feeding groove occurring in the flagellated members of the group and further expanded via molecular studies. The Excavata contains many human disease-causing representatives including *Giardia* (diplomonad), *Naegleria* (heterolobosean), and *Trypanosoma* (kinetoplastid), as well as many free-living nonpathogenic members. Among them is *Euglena* that includes both heterotrophic and autotrophic representatives. As with other supergroups, the Excavata also contains members that are multicellular, namely, heterolobosean acrasids that form a sporangia much like the slime molds of the Amoebozoa – but phylogenetically distinct. Also like slime molds, they serve as major decomposers in the environment.

Future Directions

With increasing numbers of rRNA-based environmental clone surveys unveiling potentially novel eukaryotic groups, there is still the chance that there remain unexplored supergroups of the domain Eukarya (Massana and Pedros-Alio 2008). Among the possibilities are sequences related to Apusomonads and Picobiliphyta, two protist groups that do not have clear affinities to existing supergroups. New technologies afforded

by next-generation pyrosequencing (Amaral-Zettler et al. 2009) and single-cell ► [genomics](#) approaches hold promise for completing our search for novelty among the Eukarya.

Definition

Eukaryotes are the organisms belonging to the phylogenetic domain Eucarya. Eukaryotic cells are less diverse than ► [prokaryotes](#) (phylogenetic domains ► [Archaea](#) and ► [Bacteria](#)), but have a complex cellular architecture comprising a ► [nucleus](#), a cytoskeleton (a proteinaceous network structuring the cytoplasm to facilitate intracellular traffic, endo- and exocytosis, phagocytosis, cellular division, cell membrane and wall deformation and amoeboid locomotion), an

endomembrane system (a system of internal membranes subdivided into several organelles and used for synthesis, processing, packaging, and transport of macromolecules such as lipids and ► [proteins](#)), and organelles such as mitochondria (or derived organelles) and ► [chloroplasts](#) in photosynthetic eukaryotes.

Overview

Unicellular eukaryotes are called protists. They are very diverse and occur in all the supergroups of the eukaryotic tree (Burki et al. 2020). Multicellular eukaryotes include fungi, animals, algae, and plants. Models for the origin of eukaryotes are numerous, including a phagotrophic origin (e.g., Cavalier-Smith and Chao 2020) or a syntrophic origin with the association of prokaryotes – one archaeon and one or more bacteria – to form FECA, the first eukaryotic common ancestor (e.g., Moreira and López-García 1998; Martin and Müller 1998; López-García and Moreira 2015, 2019; Bulzu et al. 2019; Imachi et al. 2019; Spang et al. 2019). Recently, new clades of archaea called Asgard were discovered, and their genes indicate that they include the closest relatives to eukaryotes (Spang et al. 2019). However, other studies propose a closer relationship between eukarya and planctobacteria, and that archaea are sister, not ancestor of eukarya (e.g., Cavalier-Smith and Chao 2020; Devos 2021). One Asgard archaeon was isolated from deep sea sediment and successfully cultivated (Imachi et al. 2019). This tiny (550 nm) anaerobic slow-growing archaeon degrades amino acids through syntrophy, and shows no internal organelles (nor nucleus), but has long, often branching protrusions and genes of a cytoskeleton (Imachi et al. 2019).

Eukaryogenesis is “the whole sequence of evolutionary events occurring between FECA and LECA the last eukaryotic common ancestor (or the most recent ancestor of all modern eukaryotes), explaining the process by which eukaryotic cells emerged from prokaryotic ancestors” (Eme et al. 2017).

To date, the timing and relative order of evolution of eukaryotic cellular features characterizing

LECA, such as the nucleus, endomembranes, cytoskeleton, meiosis, and mitochondria, is unknown (Koumandou et al. 2013; Ettema 2016; Dacks et al. 2016; Eme et al. 2017; Martin et al. 2017; Roger et al. 2017). Based on comparison with Asgard Archaea genomes, FECA probably had key elements of the cytoskeleton and vesicle budding and trafficking, suggesting that some cellular complexity may have emerged before the mitochondria (Eme et al. 2017). The mitochondrion derives from an alpha-proteobacterium ancestor but several scenarios exist for the timing of its acquisition: at an “early” stage coinciding to the birth of FECA, an “intermediate” stage between FECA and LECA, or a “late” stage with the birth of LECA (Ettema 2016; Roger et al. 2017). The age of LECA is also debated, based on the interpretation of the fossil record and on estimations by molecular clocks, ranging from an early LECA in the late Paleoproterozoic (1.9–1.7 Ga) (Javaux 2011; Parfrey et al. 2011; Eme et al. 2014; Butterfield 2015; Javaux and Knoll 2017; Betts et al. 2018; Javaux et al. 2021) to a late LECA in the Meso- to Neoproterozoic (0.7–1.5 Ga; Chernikova et al. 2011) or late Mesoproterozoic (1.2–1.0 Ga) (Chernikova et al. 2011; Porter 2020) or early Neoproterozoic (1.18–0.74 Ga; Cavalier-Smith and Chao 2020).

Regardless of fossil interpretation or taxonomic identification, the evolution of biological innovations can be preserved in part – or inferred from the morphology, ultrastructure, and chemistry of early eukaryotes. It can be traced back through time and inform on the timing and pattern of eukaryogenesis and diversification of stem and crown clades (Javaux et al. 2003, 2004; Javaux and Marshal 2006; Javaux 2007, 2011; Knoll 2014; Knoll et al. 2006; Javaux and Knoll 2017; Butterfield 2009, 2015; Porter 2020). In addition, artificial fossilization (taphonomic) experiments may also permit to test the possible preservation of soft tissues and cellular organelles in the geological record (e.g., Carlisle et al. 2021).

The early eukaryotic fossil record includes carbonaceous compressions where the organic-walled microscopic or macroscopic organisms are preserved flattened parallel to fine-grained

clay-rich rocks (shales and siltstones), parallel to rock bedding; permineralized fossils where the organic and/or mineral parts of organisms are preserved three-dimensionally in silica (chert); molds and casts of microscopic and macroscopic remain where their original organic or mineral components have been replaced by other minerals (carbonate, phosphate, pyrite, silica); mineralized skeletons, walls, or scales preserving their original mineralogy; and phylogenetically informative molecules (molecular biomarkers) (Javaux 2011). Among microfossils, ► *acritarchs* include the oldest eukaryotic fossils. They are organic-walled hollow vesicles with unknown biological affinities, rare in the Archean and in the late Phanerozoic, common in the Proterozoic and early Phanerozoic. The origin of the domain Eucarya (the age of FECA) is not constrained and might be an Archean event. However, the Archean eukaryotic record is debated. Previous reports of biomarkers (fossil molecules), possibly indicating the presence of cells able to synthesize eukaryotic sterols in their flexible membranes, were reassessed as contaminants. Molecular phylogenies indicate the capacity to synthesize sterols in bacteria, probably in stem eukaryotes and in aerobic LECA (Goldman and Summons 2009; Desmond and Gribaldo 2009; Hoshino and Gaucher 2021), but crown-group eukaryotic

biomarkers are confirmed only in the Neoproterozoic (0.8 Ga) (Brocks et al. 2017) and in the Mesoproterozoic (1.4 Ga) (Zhang et al. 2021). Large unornamented organic-walled microfossils reported in the 3.2 Ga Moodies Group, South Africa, are enigmatic and could be prokaryotic or eukaryotic (Javaux et al. 2010). Older possible microfossils, some with flanged lenticular shapes, are reported in 3.4 Ga Strelley Pool Formation from the Pilbara in Australia, but the biogenicity of the morphologies is discussed (review in Javaux 2019).

The earliest unambiguous eukaryotic fossils are about 1.75–1.65 Ga acritarchs with organic walls ornamented by concentric striations, plates, or spines (ca. 1.78–1.73 Ga McDermott Formation, Australia, Javaux, 2021; ca. 1.67–1.63 Ga Changcheng Group, China, Miao et al. 2019; >1.65 Ga Mallapunyah Formation, Javaux et al. 2004; Javaux 2019; ca. 1630 Deonar Formation, Vindhyan Supergroup, India, Prasad et al. 2005). In the Mesoproterozoic, the eukaryotic microfossil record shows higher diversity and more obvious ecological heterogeneity (Beghin et al. 2017; Javaux and Knoll 2017). The first process-bearing acritarch (*Tappania plana*, Fig. 1) appears and is interpreted as eukaryotic based on the combined characters of its complex ornamentation, large size, and decay-resistant wall (Javaux et al.

Eukaryotes, Appearance and Early Evolution of, Fig. 1 Examples of fossil eukaryotes. (about 200 μm in diameter) with an organic wall made of imbricated plates, interpreted as an early eukaryote from the 1.65 Ga Ruyang group, China, Australia. (Photo: E. Javaux). Right: *Bangiomorpha*, a multicellular red alga, from the 1.047 Ga Hunting Formation, arctic Canada. (Photo: N. Butterfield)

2001). It occurs in several late Paleoproterozoic to Mesoproterozoic strata worldwide with other protists with ornamented walls. Another early protist has a complex morphology with wall bearing processes (spines) and made of organic scales (*Shuiyousphaeridium macroreticulatum*, Fig. 1) found in the <1.74 to >1.41 Ga Ruyang Group, China (Javaux et al. 2004; Agić et al. 2017). These and other associated early microfossils display characters of a eukaryotic degree of organization and are interpreted as eukaryotes with a sophisticated cytoskeleton and endomembrane system (review in Knoll et al. 2006; Javaux and Knoll 2017). They probably lived in slightly oxygenated niches close to cyanobacterial mats (Javaux et al. 2021). The earliest eukaryote that can be related to an extant clade is a multicellular red alga (*Bangiomorpha*) dated to 1.047 Ga (Butterfield 2000; Gibson et al. 2017), although fossils interpreted as red algae have been reported at 1.6 Ga (Bengtson et al. 2017), their age and identity are debated (Gibson et al. 2017; Betts et al. 2018). From the late Mesoproterozoic through the middle Neoproterozoic (1.2–0.63 Ga), possible members of several extant supergroups are recorded in the fossil record: fungi, green algae, red algae, xanthophyte algae, testate amoebae, foraminifers, ciliates, and stem metazoans (see summary in Loron et al. 2019, 2021). Major biological innovations such as multicellularity, biomineralization, heterotrophy, predation, two stages life cycle with vegetative cells and cyst and excystment structures, and eukaryotic photosynthesis appear, leading to ecological tiering and complex food webs and interactions (review in Javaux 2011; Cohen and Riedman 2018). The biases and incompleteness of the fossil and sampling records need also to be considered for diversity estimates (Cohen and Macdonald 2015; Riedman and Sadler 2017).

Complex multicellularity (tissue-grade then organ-grade organization) and animal biomineralization and predation evolved during the Ediacaran (635–542 Ma). In parallel to eukaryotic and prokaryotic evolution, simultaneously to these important biological innovations and changing ecology, the physicochemical environments in which these microbial communities

thrived also changed, with heterogeneous oxygenation of ocean and atmosphere, availability of nutrients, and large tectonic, volcanic, climatic and meteoritic impact events. However, it is still not clear how and when these physicochemical, biological, and ecological factors impacted the origin and diversification of the domain Eucarya.

EURECA

Hervé Cottin
Laboratoire Interuniversitaire des Systèmes
Atmosphériques, Université Paris Est-Créteil,
Créteil, France

Definition

EURECA (EUropean REtrievable CARRIER) was a 4.5-t satellite designed to carry spaceborne experiments for a duration of a few months. EURECA was released and retrieved by ► [NASA's](#) space shuttle. It was the first satellite designed

specifically for microgravity experiments, providing 10^{-5} g conditions for long periods.

An important feature was reusability: EURECA was built to survive during five flights over a 10-year period. However, it was used only once, due to lack of funding.

EURECA-1 and its 15 experiments were launched with shuttle mission STS-46 in July 1992 and were recovered during shuttle mission STS-57 in June 1993. Among those experiments was ERA (Exobiology and Radiation Assembly) in which bacteria and organic materials were exposed to study their survival and evolution in space.

It was a precursor to the ► [BIOPAN](#) and ► [EXPOSE](#) facilities.

Galilean satellites

Definition

Europa, discovered by Galileo Galilei in 1610, is the smallest of the four Galilean satellites orbiting Jupiter. Its distance to Jupiter is 670,900 km, or about 9 Jovian radii. With a diameter of 3140 km, Europa is slightly smaller than the Moon. Its density is 3.013 g/cm^3 , typical of a mixture of rock and some ice. Its high albedo (0.67) suggests that its surface is mostly water ice. The surface temperature of Europa ranges between $\sim 125 \text{ K}$ at the equator and $\sim 50 \text{ K}$ at the poles. Galileo spacecraft

data found an induced magnetic field at Europa, suggesting the existence of a liquid water ocean underneath the near-surface ice layer. Surface morphological features as well as recent evidence for geysers are consistent with an ocean at a few kilometers to tens of kilometer depth. Underneath the ocean at about 100 km depth likely is a silicate layer mantling an iron-rich core.

Overview

Europa's exploration started with the Voyager 2 encounter in 1979. The Voyager camera revealed a strange surface topography of low-relief ridges and chaotic terrains with few impact craters. The pattern of the ridges seemed to indicate that the icy crust is detached from the interior and slightly moves with respect to it. Because Europa is subject to tidal heating due to the proximity of Jupiter (at a level of about one-tenth of that of Io), it was proposed that the icy crust of the surface might cover a liquid or viscous water reservoir. Europa then became a prime target of the Galileo mission which approached Jupiter in 1995 and explored the Jovian system until 2003. Information was retrieved about Europa's surface features, its internal structure, and its interaction with the Jovian magnetosphere.

Surface Geology

The most striking features of Europa's surface are the series of dark streaks, called *linae* which criss-cross the whole globe. They are innumerable, overlapping, up to 1000 km long and 20 km wide. In many cases, the ridges are double, often with dark outer edges and a central band. Images show that on each side of the lines, the edges have moved relative to each other. These *linae*, possibly of cryovolcanic origin, are interpreted as resulting from eruptions of warm water, in a scenario similar to the present day mid-oceanic ridges on Earth. In addition, the fracture patterns on Europa's surface are different from those expected for the case of an entirely solid planet. The old and young fractures show different orientations, with more diverse orientations the older they are. This pattern suggests that Europa's surface rotates

slightly faster than the subsurface material, which implies a liquid or viscous subsurface (Fig. 1).

Europa's surface also shows fractured and chaotic features called *lenticulae*, with diameters ranging from 10 to 100 km. Many are domes, broad bulges, which may have formed by cryovolcanic activity. Warm water may have been rising in the icy crust, in a scenario reminiscent of rising magma chambers on Earth.

Impact craters are relatively few, indicating that the surface of Europa is young. Its age can be estimated on the basis of the estimated number of comets and asteroids in Jupiter's environment and suggests an age of about 100–300 Ma. This is very young when compared to the age of the satellite. It is widely agreed that the Galilean satellites formed about 4.5 Ga ago. Most likely, Europa is still geologically active today.

Europa, Fig. 1 This color image of Europa was taken by Voyager 2 during its close encounter on July 9, 1979. The array of streaks shows that the surface has been fractured and filled in some places with material coming from the interior. The relative absence of features and craters indicates that the surface is young. (Source: © NASA)

Internal Structure and Subsurface Ocean

It is now generally accepted that a water ocean lies below the icy crust of Europa. This ocean provides the best explanation for the features observed on the surface: *linae*, *lenticulae* domes, fracture patterns. In 2000, another discovery provided the most direct evidence for the Europa ocean hypothesis: the magnetometer of Galileo detected a weak magnetic moment, induced by the varying part of the Jovian magnetic field. The existence of this induced magnetic field requires the presence of a highly electrically conductive material inside the satellite. The most plausible candidate is a large subsurface layer of liquid water. The presence of salts in this ocean is suspected from the spectral analysis of the dark surface features. Magnesium sulfate and sulfuric acids are possible candidates; sulfur components could account for the reddish color of the streaks.

What is the internal energy which keeps the water warm? Radioactive heating can support a few tens of kilometers thick ocean as thermal models suggest, but tidal heating is likely an even more effective energy source. Europa is likely to be differentiated with a central core of iron and some lighter element such as possibly sulfur, surrounded by a silicate mantle and then by water-rich ocean with an ice crust. Europa's orbit around Jupiter is slightly eccentric and is in orbital resonance with Io and Ganymede. Consequently, although it is in synchronous rotation with Jupiter (showing always the same face to Jupiter), the tidal bulge raised by Jupiter oscillates slightly in height and orientation as Europa moves along its orbit. As a result, energy is dissipated inside Europa and models indicate that the maximum dissipation may take place in the lower part of the ice layer. But dissipation in the silicate mantle is a possible alternative that would provide a mechanism for the delivery of nutrients to the ocean through silicate volcanism. In 2008, scientists proposed that another efficient energy source might come from large planetary tides, generated by Rossby waves, due to the nonzero obliquity of the satellite.

What could be the thickness of the ice crust? According to the models, it could range between a few kilometers and a few tens of kilometers. The

study of Europa's largest craters, surrounded by concentric rings and filled with flat and fresh ice, suggests a 10–30 km thick ice crust, including a ductile warm ice layer, over a liquid ocean which might be about 100 km deep. This thickness would also be consistent with ice shell tidal heating. According to most models of internal structure, the liquid ocean is expected to be in direct contact with the silicate mantle.

An important result has come recently from the reanalysis of Galileo images of chaos. This work suggests that these areas are formed above liquid water lenses located within an ice shell as shallow as 3 km. Although drilling the surface of Europa at 3 km depth is beyond our present capabilities, this result, if confirmed, would have significant implications for astrobiology.

Transient Atmosphere

In 1995, HST observations revealed that Europa has a very thin atmosphere mostly composed of molecular oxygen O_2 , with a surface pressure of about 10^{-12} bar. Two years later, the Galileo spacecraft identified also a tenuous ionosphere resulting from the interaction of Europa's surface with high-energy particles of the Jovian magnetosphere. This magnetosphere carries a dense plasma of energetic sulfur and oxygen ions which have escaped from Io. The trailing hemisphere of Europa is especially exposed to this effect, as shown by the darkening of its UV spectrum. The colliding ions eject water molecules from Europa's surface (this is the "sputtering effect"); as some of them leave to space, the surface is slowly eroded: erosion rate is estimated at about 5–20 cm per million years. This provides additional evidence that the surface of Europa is relatively young. The surface sputtering is also responsible for the molecular oxygen tenuous atmosphere. O_2 is the major atmospheric component because it does not freeze at the equator. Hydrogen peroxide (H_2O_2) ice has been also detected on Europa by the Near Infrared Mapping Spectrometer of Galileo, and hydrogen peroxide acid mixtures might account for some of the features of the surface spectrum. Molecular hydrogen cannot remain on Europa's surface because the satellite's gravity field is too low. It escapes in a

torus, along with atomic and molecular oxygen, to form a neutral torus along the orbit of Europa. This torus has been identified by the Galileo and Cassini spacecraft.

In 2016, water plumes were episodically detected on Europa by the HST, possibly indicative of cryovolcanic activity, as on Saturn's satellite Enceladus. In 2018, this result was confirmed by a reanalysis of Galileo data of 1997, providing new evidence for the presence of a water ocean below the icy crust.

Potential for Extraterrestrial Life

Europa's interior is considered as a possible candidate for extraterrestrial life in the solar system. Indeed, there are three conditions which seem to be required for the development of life on Earth: the presence of carbon, an energy source, and liquid water. Many carbon-rich compounds have been found in comets and meteorites, and such elements may have been brought to Europa by meteoritic impacts. Even if impact craters have been filled in by resurfacing, Europa probably underwent an intense meteoritic bombardment similar to Ganymede and Callisto. The energy source, as discussed above, is provided by tidal heating together with radioactive heating. Life could exist in an ocean underneath the ice crust in an environment comparable to the Earth's hydrothermal vents or the Antarctic lake Vostok. On Europa, free radicals delivered by subduction of surface ice may provide a sufficient source of free oxygen, even in the absence of photosynthesis. Life on Europa, if it exists, could be clustered around hydrothermal vents on the ocean floor. Similarly to what we find on Earth, a process called serpentinization could occur in Europa's ocean as seawater reacts with rock to form new minerals, releasing hydrogen. Alternatively, life could exist clinging to the lower surface of Europa's ice layer, much like algae and bacteria in Earth's polar regions, or float freely in Europa's ocean. If Europa's ocean is too cold or too salty, only extremophiles could survive in its environment.

It should be recalled that there is no any evidence that life exists on Europa today. However, there is a large consensus in the scientific

community about the existence of an ocean of salty liquid water, probably in contact with a silicate mantle to account for the salty content, under an icy crust which is probably several kilometers or several tens of kilometers thick. It remains however to be determined if some of life's other major constituents like carbon, nitrogen, phosphorus, and sulfur also exist in the ocean and at what quantities. The fact that Europa is a potential candidate for extraterrestrial life or at least for habitable conditions has motivated the scientific community for designing two ambitious missions. Jupiter Icy moons Explorer (JUICE) has been selected by ESA for launch in 2022 and arrival in the Jupiter system in 2030. The spacecraft will achieve several flybys of Jupiter and the Galilean satellites, including two flybys of Europa, and will be put in orbit around Ganymede in 2033 for an in-depth exploration of the habitability conditions of the icy moons. Europa Clipper, developed by NASA, is planned for launch in the early 2020s for an arrival in the Jovian system between 3 and 6 years later, to perform a series of 45 close flybys of the satellite. The main challenge for both spacecraft is how to survive in the high radiation field generated by the magnetic field of Jupiter and hence a lander concept is still only in study phase.

Europa Analogues

Felipe Gomez

Centro de Astrobiología (CSIC/INTA), Instituto Nacional de Técnica Aeroespacial, Torrejón de Ardoz, Madrid, Spain

Keywords

Antarctica · Jupiter · Europa

Definition

Extreme field sites on Earth that mimic some of the conditions on Jupiter's moon Europa are considered Europa analogues. Some Earth natural field sites are extreme, due to very low temperature, high salinity, or high pressure conditions. These extreme conditions partially characterize the environment of Europa. Lake Vostok in Antarctica is one of the best recognized Europa analogues. Due to the thick ice crust, a liquid water reservoir underneath is stable due to salinity and high pressure conditions. Lake Tirez in La Mancha (Spain) is considered a geochemical analogue of Europa due to the ionic content of its waters.

Acronyms

EAI

Definition

The European Astrobiology Institute (EAI) is a virtual institute consisting of more than Around 20 research and higher education institutions in the European Research Area as well as European research bodies and infrastructures. It aims to create a European environment of research, training, and public engagement in astrobiology. To achieve its goals, the EAI cooperates with entities engaged in education on all levels and public authorities promoting science (e.g., museums, space agencies, adult training centers, etc.) as well as industries and other stakeholders. The EAI was founded in 2019. Further information is available at the website: <http://www.europeanastrobiology.eu>.

European Space Agency

William M. Irvine

Department of Astronomy, University of Massachusetts, Amherst, MA, USA

Definition

The European Space Agency (ESA) was established in 1975 and is responsible for

coordinating the exploration of space by its member countries, which numbered 22 in 2021: Austria, Belgium, Czech Republic, Denmark, Estonia, Finland, France, Germany, Greece, Hungary, Ireland, Italy, Luxembourg, the Netherlands, Norway, Poland, Portugal, Romania, Spain, Sweden, Switzerland, and the United Kingdom, with Canada as an associate member. In addition, Bulgaria, Cyprus, Malta, Lithuania, and Slovakia have cooperation agreements with ESA. ESA's program includes human space flight, primarily through participation in the ► [International Space Station](#), and a variety of scientific missions. Of particular interest to astrobiology is Gaia, an all-sky astrometric survey mission that will detect hundreds, if not thousands, of extrasolar planets. Other exoplanet missions include Cheops (launched in 2019), Plato, and Ariel. ESA is also committed to the exploration of ► [Titan](#) with the successful landing at the surface of the satellite of the ► [Huygens probe](#) in 2005, the exploration of Jupiter's icy moons with JUICE, and in the exploration of comets with the Giotto mission in 1986 and the Rosetta mission, launched in 2004 and orbiting the target comet from 2014 to 2016, and the planned Comet Interceptor Mission. Current and future missions also focus on the exploration of Mars and the question of whether life exists, or has ever existed, on the planet. The Mars Express mission has been in orbit since December 2003, while the ExoMars program includes the Trace Gas Orbiter launched in 2016, a rover and surface platform planned for 2022 together with the Russian space agency Roscosmos, and cooperation with NASA for a Mars sample return to Earth.

Euryarchaeota

Ricardo Amils

Departamento de Biología Molecular,

Universidad Autónoma de Madrid, Madrid, Spain

Definition

Euryarchaeota is one of the best characterized superphylum of the domain ► [Archaea](#). The extremophiles used by C. Woese to discover the existence of Archaea belong to this phylum. Euryarchaeota comprises a physiologically diverse group of Archaea: all known methanogens, extreme halophilic Archaea, ► [hyperthermophiles](#) such as *Thermococcus* and *Pyrococcus*, most acidophilic-thermophilic prokaryotes including *Picrophilus*, and the thermophilic-acidophilic cell wall-less *Thermoplasma*. A large number of Euryarchaeota produce methane (CH₄) as an integral part of their metabolism (see ► [methanogens](#)). It is considered a very ancient metabolism due to the unique set of enzymes involved. The extreme halophilic Archaea are a diverse group of Euryarchaea that inhabit highly saline environments (see [halophile](#)). Most species require 2–4 molar salt concentration for optimal growth, and they are able to

grow in the presence of saturating salt conditions. *Picrophilus* is capable of growing below pH 0. *Pyrococcus*, which literally means fireball, has an optimal growth at 100 °C.

Evaporite

Daniele L. Pinti

Geotop, Research centre for the dynamics of the Earth system, Université du Québec à Montréal, Montréal, QC, Canada

Synonyms

[Evaporitic rocks and minerals](#)

Definition

Evaporite is a class of sedimentary rocks and minerals precipitated from evaporating brines. Common evaporitic minerals calcite (CaCO_3), dolomite ($\text{CaMg}(\text{CO}_3)_2$), anhydrite (CaSO_4), gypsum ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$), and halite (NaCl) precipitate out of solution in the reverse order of their solubilities

from evaporating seawater. Non-marine evaporites such as trona ($\text{Na}_3\text{H}(\text{CO}_3)_2 \cdot 2\text{H}_2\text{O}$) can be precipitated in soda lakes. The occurrence of evaporite minerals on planetary surfaces may record the past presence of water. The Mars Rover Opportunity has discovered gypsum and ► [jarosite](#) in the Burns Formation, *Meridiani Planum*, Mars, which are interpreted as deposits formed by the evaporation of acidic waters of likely hydrothermal origin (e.g., McLennan et al. 2005).

Evaporites, Archean

Sami Nabhan

Institute of Geological Sciences, Freie Universität Berlin, Berlin, Germany

Keywords

Evaporites · Barite · Gypsum · Carbonate · Chert · BIF · Archean · Continental growth

Definition

Evaporites are chemical sediments and sedimentary rocks that form as result of an increasing concentration of ions in water as precipitates

either at the surface or at the base of the water body. The majority of evaporitic sediments and sedimentary rocks on Earth consist of carbonates, sulfates, or halides. Archean evaporites are, to their largest part, either of a restricted-marine facies or hydrothermally related. Open-marine evaporites are completely absent, terrestrial evaporites nearly so.

Overview

Evaporites compose a disproportionally small percentage of the Archean rock record because their preservation potential is generally low and because conditions for their formation may have been poor due to smaller and fewer emerged ► [continents](#), lower continental freeboard, a perceived hot and humid climate, and an unknown saturation state of the oceans. Ocean salinity and surface water temperature are major controlling factors for the precipitation of evaporites. Estimates of the Archean ocean temperature based on oxygen isotope composition of early diagenetic ► [chert](#) units are debated, as is the salinity of Archean ocean water. Archean ocean temperatures, as indicated by the isotope composition of Archean cherts, were approx. 55–85 °C (Knauth 2005), while a more recent reevaluation of data, based on both oxygen and silicon isotopes, provides Archean ocean temperature ranging between 35 °C and 55 °C (Marin Carbonne et al. 2014). Estimates of Archean ocean water salinity based on “adding back” the volume of halite in the geological record to the oceans would result in a salinity of 1.2–2 times the modern value (Knauth 2005). This number, however, is highly dependent on estimates of the size of subsurface salt deposits and of hypersaline brines in sedimentary basins. Other factors controlling evaporation include the ionic composition of Archean ocean water and its pH value. The suggestion of an early ocean saturated in sodium carbonate (the “soda ocean”) would result in a pH of ~10 (Kempe and Degens 1985; Gargaud et al. 2005). The presence of reduced iron (Fe^{2+}) in the Archean ocean, however, indicates a pH between 6 and 7 (Krissansen-Totton et al. 2018).

Archean evaporites are commonly preserved as pseudomorphs, silicified from their precursors (e.g., gypsum ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$), nahcolite (NaHCO_3), and aragonite (CaCO_3)). Most evaporites are preserved as dolostones and limestone that originally precipitated as carbonate cements such as aragonite and magnesian calcite (Grotzinger and Kasting 1993) or as ► [stromatolites](#), a common component of Archean carbonate platforms (Grotzinger and James 2000). Most carbonates older than ~3 Ga are of peritidal sedimentary facies and found in ► [greenstone belts](#) of South Africa, Australia, and India (Harnmeijer 2010). The oldest known carbonate platform is the ~2.9-Ga-old Steep Rock platform in Ontario, Canada. At about 2.6 Ga, platform-type carbonates became established (Grotzinger and Kasting 1993; Harnmeijer 2010), substantially composed of original aragonite (now mainly dolomitized) and exemplified by the ~2.55-Ga-old Campbellrand-Malmani carbonate platform with individual beds of up to 65% encrusting carbonate. This suggests that seawater was supersaturated with respect to aragonite and calcite and that its pH was neutral to slightly alkaline (Sumner and Grotzinger 2004). In some Neoproterozoic carbonate platforms, the presence of pseudomorphs of carbonates and chert after halite (NaCl) crystals combined with an absence of sulfate pseudomorphs within supratidal lithofacies zones (Boulter and Glover 1986; Sumner and Grotzinger 2004; Eriksson et al. 2005; Gandin et al. 2005) has been interpreted to either reflect a generally low sulfate content or, as a consequence of extensive carbonate precipitation, a low calcium content of seawater (Boulter and Glover 1986; Grotzinger and Kasting 1993; Sumner and Grotzinger 2004; Eriksson et al. 2005). On the other hand, pseudomorphs after swallowtail gypsum and enterolithic gypsum have been described by Gandin et al. (2005). Some of the crystal fans interpreted as aragonite fans resemble gypsum domes in their structure (Hardie 2003; Gandin et al. 2005). Calcitization of former sulfate evaporites is interpreted as a result of bacterial sulfate reduction and the organic diagenesis of pyrite (FeS_2) (Gandin et al. 2005). Such a metabolic process would constitute a second link to

widespread microbial life in the Archean, aside from the abundant morphological evidence provided by stromatolites in carbonate platforms.

Sulfate deposits formed as thinly bedded barite (BaSO_4) of early and mid-Archean age are well represented in the ~3.3-Ga-old Sargur Group, ► [Dharwar Craton](#), central India (Jewell 2000); the ~3.45-Ga-old Onverwacht and the ~3.24-Ga-old Fig Tree Groups of the ► [Barberton Greenstone Belt](#), South Africa (Lowe et al. 2019); and the 3.45-Ga-old North Pole chert-barite unit of the Warrawoona Group, Western Australia (Jewell 2000). All of them are of marine origin and show primary sedimentary and secondary diagenetic structures (Buick and Dunlop 1990; Jewell 2000). For some deposits, their possible origin by volcanic-hydrothermal exhalation is discussed (Reimer 1980). Parts of the North Pole barite have been interpreted as pseudomorphosed gypsum, based on interfacial angles of individual crystals (Buick and Dunlop 1990; Jewell 2000; Shen et al. 2001). ► [Sulfur isotope](#) variations within these sulfates in microcrystalline ► [pyrite](#) suggest the existence of sulfate-reducing bacteria (Shen et al. 2001; Shen and Buick 2004; Dunlop 2015).

Overall, the presence of evaporitic sulfates in the 3.5–3.2 Ga Archean rock record may indicate a global sulfate-bearing, partly oxidized, and stratified ocean (Huston and Logan 2004). Aside from the three deposits mentioned above, only two additional bedded sulfate deposits are known in the geologic record prior to the GOE at ~2.4 Ga, after which they become more abundant (Huston and Logan 2004), possibly due to low concentrations of sulfate in the Archean ocean (Boulter and Glover 1986; Grotzinger and Kasting 1993; Sumner and Grotzinger 2004; Eriksson et al. 2005; Gargaud et al. 2005). However, a partly oxidized ocean may not be required to produce low seawater sulfate from volcanic SO_2 because SO_2 reacts with H_2O to H_2S and H_2SO_4 even in the absence of oxygen (Huston and Logan 2004; Gargaud et al. 2005).

Terrigenous evaporites are exceedingly rare in the Archean. Nabhan et al. (2016) describe widespread silicified former sulfate nodules from the vadose zone of fluvial to supratidal coastal plains

of the ~3.2-Ga-old Moodies Group, South Africa, and interpreted them to have formed pedogenic to early diagenetic by evaporating groundwater in semiarid conditions.

Some Archean cherts and possibly banded-iron formations (BIF) can be considered evaporites where the involvement of biologic processes is uncertain or unlikely. Some cherts may form abiogenically in subtidal environments due to silica oversaturation of pore waters during evaporation (Pufahl and Hiatt 2012). ► [Banded-iron formations](#) are composed of a mixture of silica with iron-bearing minerals such as hematite (Fe_2O_3), magnetite (Fe_3O_4), siderite (FeCO_3), and pyrite (FeS_2), which precipitate depending on ocean water chemistry (Huston and Logan 2004; Gargaud et al. 2005; Pufahl and Hiatt 2012). They are interpreted either as deep-water precipitates or as precipitates developed during times of restricted clastic supply.

Basic Methodology

- Field observations (mapping, documentation of sedimentary structures, construction of stratigraphic cross sections)
- Thin-section microscopy
- Analysis of major and trace element distribution
- Raman spectroscopy for fluid and gas inclusions
- Stable isotope fractionation (S, C, O, N, Sr, Fe)

Applications

Evaporites are sedimentary rocks that reflect atmospheric and hydrospheric conditions during the time of their formation. Therefore, Archean evaporites can be used to constrain Archean atmospheric and seawater composition. Terrestrial evaporites can also be used to provide information on Archean groundwater and to infer climatic conditions. Evaporites are often related to or aided by biogenic processes and may thus preserve traces of early life.

Evidence in Astrobiology

Erik Persson

Department of Philosophy, Lund University,
Lund, Sweden

Keywords

Evidence · Justified belief · Reasons for belief ·
Proof · Biosignatures · Technosignatures

Synonyms

The term “proof” is sometimes used in common language as a synonym to “evidence,” though in philosophical and strict scientific jargon, proof is usually referred to mathematics and logic, and is not used in connection with empirical science. Contrary to proof, evidence is not a matter of either-or but of strength. Thus, evidence for X of strength Y justifies belief X to degree Y. Contrary to proof there can also exist evidence both for and against a belief.

Definition

‘Evidence’ is defined by the Cambridge dictionary as “one or more reasons for believing that something is or is not true” (The Cambridge Dictionary).

In philosophy, evidence is also often defined in terms of justification, rather than reason, for belief. A probabilistic definition would look as follows:

E is evidence for H if and only if $P(H|E) > P(H)$.
E is evidence against H if and only if $P(H|E) < P(H)$, though whether evidence is best described in probabilistic terms is controversial (The Stanford Dictionary of Philosophy 2014).

Overview

Astrobiology is an interdisciplinary field that tries to answer some connected yet different questions.

This makes the question of evidence slightly more complicated than in most other fields. The question is complicated further by the fact that the questions asked by astrobiology have strong relevance also outside of science, including among the general public.

Among the key issues, we find the following questions:

- “What counts as evidence in astrobiology?”
- “How do we assess the strength of evidence in astrobiology?”
- “Do different questions need different kinds/strength of evidence?”
- “What kind/strength of evidence do we need to establish that life has been found on a particular celestial body?”
- “What kind/strength of evidence do we need to establish that a particular body is uninhabited?”
- “What kind/strength of evidence do we need to establish that we are alone in the universe?”

Extraordinary Claims Require Extraordinary Evidence

The most commonly cited statement about evidence in astrobiology is “extraordinary claims require extraordinary evidence,” also known as the Sagan standard. The quote is from Carl Sagan’s TV-series *Cosmos* (Sagan 1980), but the idea behind the statement can be traced back most noticeably to Laplace (1812) and Hume (1748).

Though the statement makes intuitive sense, it also raises questions. How can different claims to truth require evidence of different strength; what makes a claim extraordinary; what kind of or amount of evidence counts as extraordinary, and in our case, what answers to what questions in astrobiology should count as extraordinary? Is for instance a claim that there is life on another world, more or less extraordinary than a claim that we are alone in the universe? Is an alleged finding of extraterrestrial intelligent life more or less extraordinary than an alleged finding of extraterrestrial microbial life?

The nature of these questions also makes the Sagan standard difficult to operationalize.

The need for extraordinarily strong evidence in astrobiology must also be balanced against the

need to avoid feeding into conspiracy theories. If the demand for extraordinary evidence leads to rejection of conclusions that under normal circumstances would be accepted by the scientific community or if the publication process takes an unusually long time, there is a risk that this will feed the myth that the scientific society knows more about extraterrestrial life than they want to admit to the public.

Biosignatures

Directly observing life on another world is difficult, especially outside our solar system. Evidence for life can, however, also be in the form of non-living phenomena, referred to as biosignatures. A biosignature is a non-living phenomenon that is closely enough associated with life to function as evidence for life.

A non-living phenomenon can be sufficient or necessary for life or life can be sufficient or necessary for the presence of a particular non-living phenomenon. A non-living phenomenon that does not fit into any of these categories can still be indicative of life.

Observation of a non-living phenomenon that is sufficient for life or for which life is necessary, would be conclusive evidence of life on the same level as observing actual life. Observation of a non-living phenomenon that is necessary for life would be weak evidence for life, while lack of any such phenomena on a given body is conclusive evidence that life does not exist on that body. Due to the great diversity of life and the lack of a generally accepted definition of life, it is very difficult to identify non-living phenomena as being necessary or sufficient for life as well as the other way around. A possible example of a physical condition necessary for life could be a temperature range within which chemical processes can take place. An example of a phenomenon for which (past or present) life is a necessary condition might be certain technosignatures such as Dyson-spheres (i.e., a megastructure around a star collecting a large proportion of the energy radiating from the star, see Dyson 1960) or translatable radio signals.

Non-living phenomena that do not fall into any of these categories can still provide important, though non-conclusive, evidence. The degree to which a certain non-conclusive biosignature can count as evidence in astrobiology depends not just on its own relation to life but also on the existence of alternative explanations (other than the presence of life) for the observation. The strength of O_2 as evidence of life on a particular world depends, for example, on the existence of other possible sources of O_2 on the world in question.

Collecting evidence for extraterrestrial life is thus a painstaking process that may not take the form of a discovery in the traditional sense but rather be a matter of increasing the amount and quality of evidence until we decide that we are certain enough. This means we have several problems to consider: How certain do we have the right to be given the evidence we have? What kind of evidence do we need in order to increase the certainty, and how do we collect such evidence? Where on the scale do we need to be in order to be certain enough to declare that we have actually found life?

How we answer the last question regarding when we can be certain enough, is not an empirical but a philosophical question Persson 2014. It depends, among other things, on the purpose of the question and the values at stake. For example, is it about being confident enough that we found life to publish a scientific paper or to hold a press conference, or is it about being confident enough that a world is uninhabited to move the planet to a different planetary protection category or to allow commercial exploitation of the planet?

The Evidence Value of Non-findings

If we, in spite of trying, do not find any reliable evidence for extraterrestrial life on a particular world, or anywhere, how shall we interpret that information? Is lack of evidence for life the same as evidence against life? The answer to this question is that the relation between positive findings and non-findings in terms of evidential value is asymmetric. The evidential value of non-findings is not comparable in strength to the evidential value of positive findings but that does not mean

they have zero evidence value (Achinstein 2003; Chalmers 1999; Noble 1975; Popper 1959). If we drop a stone 10,000 times and it falls to the ground every time, we can still not be as certain that it does not sometimes fly off on its own, as we can be that it sometimes falls to the ground. Even so, it is more rational to bet that it will fall to the ground than that it will fly away next time we drop it. This means we can successively increase our confidence that a world is uninhabited by gathering negative evidence, just as we can successively increase our confidence that a world is inhabited by gathering more and better evidence, even if none of the evidence is conclusive. The collective strength of any amount of non-conclusive evidence whether positive or negative, cannot reach the same level of confidence as one piece of conclusive evidence but we can get asymptotically closer by continuing to gather more and better evidence. (Note, however, that conclusive evidence means that we are justified in believing something beyond doubt. It is not the same as proof in mathematical or logical context.) Like with positive evidence, different non-findings can have different strengths depending on the quality of the study. A good study that does not find anything is stronger (though still in itself rather weak) evidence against life than a poor study that does not find anything. A certain number of non-findings from studies focusing on different places or biosignatures or use different methods are also, taken together, stronger evidence than the same number of studies with less variation. The problem of deciding where on the evidence scale we need to be to decide that we are certain enough and for what purpose, will be same as with positive evidence.

In principle, the same goes for evidence that we are alone in the universe, but due to the sheer size of the universe, the evidence value of each non-finding will be very small.

Evo-devo

Stéphane Tirard

Centre François Viète d'Histoire des Sciences et des Techniques EA 1161, Faculté des Sciences et des Techniques de Nantes, Nantes, France

Definition

“Evo-devo” is the term used to designate the relationship between evolution and developmental biology. It corresponds to the evolutionary developmental biology. This term “evo-devo” was created in the 1980s, after the discovery of the genes that regulate development of the animal body, notably the *Hox* gene complex.

During the last decades, the expansion, the distribution, and the changes in the embryonic expression of these genes in taxa have been associated to explain evolutionary changes in animal organization.

Evolution of Species, Islamic Ideas

Salman Hameed
Hampshire College, Amherst, MA, USA

Keywords

Evolution · The great chain of beings · Al-Jahiz · Brethren of Purity · Ibn-Miskawayh

Definition

There are few medieval Islamic scholars who speculated on the evolution of species (e.g., Al-Jahiz, Ibn-Miskawayh, and a group of writers using the pen name the Brethren of Purity). In most instances they believed in the creation of species by God and a hierarchy of God's creation from minerals, plants, and animals to humans, angels, saints, and prophets. Al-Jahiz, however, did comment on the interconnectedness of life and described an ecosystem based on the adaptation of species to local environment, but the Brethren of Purity considered adaptation as a gift from God rather than a process responding to environmental conditions.

Overview

There are diverse claims about medieval Islamic ideas on the evolution of species and there is limited scholarship available on this topic. Some of the uncertainty lies in the late nineteenth- and twentieth-century translations and interpretations of medieval works in light of Darwin's theory. Sarton (1927) and Bayrakdar (1983) made strong claims that Al-Jahiz (776–886 C.E.) in his book, *The Book of Animals* (*Kitab al-Hayawan*), came close to natural selection and some form of a theory of evolution. Egerton (2002) disputes the strong claim but attributes the origin of a detailed idea of a food chain to Al-Jahiz. According to Elshakry (2014), *The Book of Animals* was more a work of literature “written in a highly expressive

and ornate style...with its emphasis on philosophical and religious edification” rather than a zoological treatise. Al-Jahiz believed in spontaneous generation of life, but he commented on the interconnectedness of life and believed that every plant and animal had its place in the scheme designed by God. It is in this context that he described ecosystems and commented on adaptation of species, where stronger animals “feed upon weaker species than itself” and that “each animal is the food for a species that is stronger than itself” (Stott 2013). The works of Ibn-Miskawayh (940–1030 C.E.) and a group of tenth-century pseudonymous writers in Basra known as ► *Ikhwan al-Safa* (Brethren of Purity) drew on the idea of the *Great Chain of Being* that connected all life (and also minerals, with alum and vitriol being the lowest types) in a hierarchical structure, but then speculated on the possibility of transformation of species within the ladder. While apes are mentioned to be close to humans, their hierarchical structure also includes angels, saints, and prophets, thus making it hard to argue for a straightforward theory of evolution (Elshakry 2014). The *Ikhwan* are considered keen observers of the biological world, but consider adaptation as God's grace to the species rather than a process. Similarly, while they do identify some animals as intermediate species (e.g., they call the giraffe a cross between a camel and an ass), they still see these as stable forms of its kind (Goodman and McGregor 2009). Much of the uncertainty in the interpretations comes from the fact that the terms used in medieval literature are “change,” “stage,” and “transformation” and scholars have to interpret this in light of the use of “evolution” (Guessoum 2011).

[Biological evolution](#)

Definition

In Biology, evolution is the change of organisms through their variation, then transmission of these variations to their progeny (whatever the way they are transmitted), and, eventually, ► [selection](#) of some phenotypic variant in the long run as a result of environmental conditions.

History

Evolution: What's in a Word?

When speaking about evolution people can have different meanings in mind even within the field of Biology. Evolution is sometimes understood as a movie scenario, a big story to tell. Evolution is

also seen, in our imaginations, as a big tree: the tree of ► [life](#). Evolution is also more or less understood as a progress. Evolution is seen as a process by which living things do change over time. Last but not least, evolution is meant as the general theory of Biology, Palaeontology, and Anthropology. The two meanings of the word that scientists would like to retain are the last two. In the eighteenth century, evolution (from latin *evolutio*, from the verb *evolvere*) originally meant the deployment of an inner content, and was employed as we use today embryonic development. The famous geologist, Charles Lyell, used the term in the sense of transformation of ► [species](#) for the first time in the second volume of his *Principles of Geology* (1832). Herbert Spencer (1862) popularized the term in a very wide sense including transformation of species through times (Tort 1996). Charles Darwin did not use the word in the first editions of his famous book *The Origin of Species* (Darwin 1859), but did in the fifth and sixth editions.

However, in a more general context, evolution is a term used to designate a change. Evolution of the political situation of a country, evolution of the social condition of workers, evolution of the health of a patient following a treatment against a given sickness, evolution of the weather, evolution of the universe, etc., are examples of common uses of the term. The question of transferring the term “evolution” to designate precise phenomena in chemistry or astronomy is meaningless if the term is understood in that general sense of “change.” The whole physical world is, obviously, subject to change. The question becomes more interesting if, by “evolution,” a particular process of change is meant. Evolution would be “change” through heritable variation of physical entities and selection of some variants by the conditions of the environment – whether biological, chemical, or physical.

Basic Methodology

Evolution in Biology: Theory and Facts

Evolution is the general theory of Biology, Palaeontology, and Anthropology. The role of a

theory is to coordinate facts, laws, models, and hypotheses, and to maximize the global consistency of the whole. A theory explains facts and allows us to predict some yet unobserved facts. When a theory is corroborated, as highly as possible, it is still a theory. Unfortunately, scientists stop speaking about their favorite theories as “theories” when their reliability is maximal. But there’s no epistemological change to justify this. As a result the public has a kind of implicit hierarchy in mind: a theory is dubious, facts are serious. But evolution is still a good theory and its role as a theory has not changed since Darwin. Its degree of corroboration is today as high as the theory of chromosomal heredity or the theory of continental drift. Hierarchy distinguishing theories from facts is nonsense for Science in general. Theories are useful to organize facts, even to simply speak about facts. Everyone should remember that cars, planes, fridges, or phones are built according to theories and not facts. There are evolutionary facts, like fossil discoveries or DNA sequences, and at the same time there is a very good theory: evolutionary theory. A theory without facts is fantasy; facts without a theory are chaos. Such an embedment of facts within theories leads to the question of theoretical changes. If facts can only make sense through a given theory, how can we change that theory for an alternate one? Usually a given fact is evaluated within (at least) two competing theories. The parsimony of a theory is the same measurement as the coherence of facts (or global consistency): the more coherent is a set of facts the less ad hoc hypotheses we need to add to maintain the theory. This is why we prefer, among the competing theories, the most parsimonious theories. Claiming that evolution “is only a theory” is therefore meaningless for scientists.

Evolution Through Multiple Sciences

Sometimes scientists are asked to provide “evidence” for evolution. Evolution being understood as a scenario, they are expected to come back from the past with pictures and films captured with their camera. Speakers in creationist or intelligent design books, websites, or “museums” claim that scientists actually know nothing from the past.

This is not true. Two epistemological sides of evolutionary sciences must be distinguished here.

First of all, evolution is supported by many experimental proofs. Organisms with short generation times are grown in the lab (fungi, bacteria, fruit flies, etc.), variation can be measured, and, knowing parameters of selective pressures, changes of variant frequencies in populations can be measured and predicted. Famous examples of experiments in evolutionary sciences of the twentieth century involved the fruit fly *Drosophila melanogaster* or the fungi *Ascomyces*. Today, it is possible to make bacteria like *Escherichia coli* perform protein engineering just by introducing selective pressures at the lab. Hypothetico-deductive reasoning is at work: if the premises and the law (or the rule) are true, the result is true. Evolutionary mechanisms are therefore either experimented/reproduced at the lab or observed in the field, and can lead to short term predictions. However, products of evolution in the wild are contingent. Each population or each species is produced by laws of mutations, recombinations, genetic drift, and ► [natural selection](#), but the result is always historically singular and cannot be predicted in the long term. One of the reasons is that all parameters of the environment undergo changes in a contingent manner. This is why evolutionary sciences are also historical sciences.

Secondly, evolution is supported by historical proofs, which are another kind of scientific proofs. If the premises are true, the result is only probable. We have a number of signs and facts. We create a scenario that maximizes consistency of the whole set of facts, minimizing ad hoc hypotheses. This is the reasoning of historians, policemen, and phylogeneticists. The reasoning is called abductive: we infer what might have occurred in the past to explain the state of facts in the present. The scenario is made *to explain* the present facts and signs. Abduction is a “reverse deduction,” deduction being found in a situation where present facts and signs would explain the scenario. By using algorithms that maximize consistency, phylogeneticists do produce statements that can be tested, i.e., reproduced or refuted, even if the reasoning is abductive.

Key Research Findings

Evolution: Biological Processes

The general process of biological evolution is based on variation. Among a set of individuals that are able to interbreed, one can notice slight differences. In the hall of the airport, at a given time no two people have the same face. This is basically due to the fact that living matter is constantly altered. Individuals belonging to the same species are not identical, and they can differ and vary in traits that are inheritable. Indeed some of the variations can be transmitted to the offspring. These varying traits are those involved in evolution. Different versions of those traits can be present in a species. Each version is (or may be) represented by several individuals. Some individuals will have a high number of descendants, others only a few, others none at all, either because the variations influence the reproductive success (selection) or just by chance (drift). We shall now examine these two processes. When the variation does not influence the reproductive output of individuals, there is no selection. In this case, each generation represents a sampling among the hereditary diversity of the preceding one. As a result the frequency of a given version of the trait does vary with time. If the global number of individuals is small, these fluctuations can have a high effect on the relative proportions of the versions within the species. This is called a “drift” in frequencies of versions. Eventually, a given version will reach a frequency of 100% or disappear just by chance. The smaller the number of individuals that can give offspring, the faster drift is (a sample differs more from the original set when it is small). The species has thus changed. If the number of individuals is high, drift is very slow and mutations which introduce variation compensates for the loss of diversity. This process constantly maintains a number of different versions within the species – this is called polymorphism. We must keep in mind that once a version has disappeared, or once a version has reached a frequency of 100%, a new version of the same trait can appear again: life is constantly altered. For example, five centuries ago the Portuguese brought domestic mice (*Mus musculus*) to the

Madeira Islands with their ships. These islands have high mountains that separate valleys. Mice settled in the valleys in small populations, almost isolated from one another. Chromosomal changes did occur. Some of the resulting chromosomal formulae reached a frequency of 100% in one valley just by drift. Those formulae, once analyzed, show that mice from one valley cannot breed with mice from the neighboring valley anymore. Reproduction is impossible because, once fecundation has occurred, genetic material cannot be harmoniously distributed among daughter cells. Populations changed, and new species (as we conventionally limit species with obstacles in the interbreeding) appeared within the past five centuries.

Charles R. Darwin (1809–1882) introduced the notion of natural selection. Among versions of a given trait, some of them confer to the individual that bears them a certain advantage in terms of number of offspring. The version of the trait is advantageous within a certain environment. If the trait is heritable and if the environment is stable enough for a while, the version of the trait can easily reach a frequency of 100% in the species. This tendency to accumulate traits favored by a given environmental condition is called ► [adaptation](#). The process is acting on many traits at the same time, as organisms are made of multiple traits. The differential reproductive success among versions of a trait (disappearing of disadvantageous versions and increase of copies of advantageous versions) is called natural selection. Note that many versions are just neutral with regard to the environment: neither advantageous nor disadvantageous. Note that drift can fix slightly disadvantageous traits just by chance. Note that selection of a strongly advantageous trait can have side effects, i.e., be accompanied with disadvantageous consequences onto another trait. There is no “perfect” organism: natural selection is a permanent trade-off among traits that are not fully independent from each other. For instance, aggressiveness is very important among female spotted hyenas. The more aggressive they are, the more they eat, the more their daughter eats, and the higher their social rank, which is transmitted to daughters (not to sons).

Males are smaller and outside this competition. Cubs are aggressive right after their birth. They fight with each other until death. Young females keep being aggressive all through their lives. Their brain had been marked by high levels of testosterone in the very early period of their development. Indeed the placenta of spotted hyenas has enzymes that transform the circulating estradiol of the mother into testosterone that circulates in the blood of the fetus. The young maintain high levels of testosterone in utero which has the advantageous consequence of early aggressiveness, but also the disadvantageous side effect of having the female external sexual organs being deviated towards a male development. As a result adult females have a peniform clitoris, an obturated vagina, a pseudo-scrotum. They give birth through the clitoris, which is a unique case among mammals. Because of this anatomical curiosity they lose 60% of their first born progeny: the umbilical duct is shorter than the corridor they must go through, provoking the separation of the placenta before the cub is out, which sometimes dies from anoxia. This gives an example – among so many others – that organisms are far from perfect and then not “designed.”

Perfection is not a scientific notion anyway, but nested within the realm of individual values. François Jacob has compared evolution by natural selection to tinkering. Contrarily to an engineer who designs the final product he wants to achieve and produces the pieces in order to reach this goal, evolution transforms existing parts through random variation and just sorts out, through selection, those which are favored within a given context. This is as if planes had been built by transforming a car. In evolution, tinkering can be seen at work in different cases. A classic example is the feathers of birds, originally selected for their thermal properties, then used for flight. One can also cite the fact that the same organ can play the role of swim bladder in some fishes or of lungs in other animals, with some intermediate forms perhaps used at both roles. Any new form is a result of a transformation of a preceding one. The development of embryos is a complex process and minor changes in the timing or functioning of each step can have important consequences on

the shape of the future individual. These variations, occurring independently from the future needs of the organism but sorted out through the relative success (in terms of survival and reproduction) of the individuals issued from them (i.e., natural selection), explain the evolution of the shape of organisms and constitute the “evolutionary tinkering.”

Natural selection has many facets: the ways by which a given version can have a higher number of descendents are many. Let's call them modalities and let's list five of them. The *first* modality of natural selection is competition among individuals of the same species for resources (food, home). This is the first one we think about because Darwin himself emphasized the “struggle for life” in his main book, an idea coming from the simple comparison between the increase of resources and the potential increase of offspring of the species exploiting them. The second increase is exponential, the first one is arithmetic: all individuals cannot get the resources they need. In other words, the populating power of a species is by far higher than the actual state of populations: if every elephant could have all the food it needs, within a few decades Africa would be all covered with elephants. There must be a competition somewhere, leading to the fact that any inheritable version of a trait that favors the ability of individuals to get more food must have led to more offspring against versions that did not confer such an advantage. However, competition for food is by far not the only modality.

A *second* modality is competition among individuals of the same sex for sexual intercourse, called sexual selection. Any change of traits favoring sexual attraction, if heritable, must have led to more offspring and must have been rapidly spread through the species. Darwin wrote an entire book about sexual selection (Darwin 1871). It is clear that there is often a trade-off between natural selection and sexual selection. A classical example is the magnificent caudal feathers of the male of the peacock. Observations and experiments led to the conclusion that such an apparatus has a real impact on females' preferences: the bigger the feathers, the higher the chance for the male to be chosen as a sexual

partner. However, the whole bulk of caudal feathers is a very long and embarrassing burden that does not allow the male to escape rapidly from predators. Such a characteristic is thus the result of a compromise between the advantage in seducing females on one side and the disadvantage in escaping from predators in the given environment.

The *third* modality of natural selection is linked to predation. The more we escape from predation, the higher the chance to transmit our traits to the offspring. Any version of any heritable trait that favors a quick escape from predators should have been selected. Here we have the origin of mimicry. The more individuals resemble their substrate, the higher their chance of survival against predation and thus the higher the size of their expected progeny. Cryptic individuals (like the famous chameleon which can adjust its color to the substrate's one, or the stick insects which are hardly distinguishable from stems or leaves) transmit their heritable traits that favor resemblance, which must have been rapidly spread if the predation pressure was high.

A *fourth* modality is the association of species. There is a gradient of situations between parasitism (association of species with a strong disequilibrium in benefits) and mutualism (association of species with mutual benefits). Our fleas are parasites. We have no benefit in hosting them. Our mitochondria are mutualist (endo)symbionts: we could not live without them inside our cells; they could not live without us. They are actually bacteria whose ancestors got associated with eukaryotic cells more than 2000 million years ago. Almost all eukaryotes are symbiotic: they have mitochondria in their cells. ► **Symbiosis** is far more spread through life than we usually think. All plants and photosynthetic algae are symbiotic: they host mitochondria and chloroplasts (another organelle produced by bacterial endosymbiosis) in their cells. All vertebrate animals are symbiotic: we harbor a variety of bacterial species in our digestive tract and we could not live without them. Symbiosis must be understood as the association of individuals from different species having both more offspring when associated than when separated. Any change that could favor

such phenomena must have been spread through generations.

A *fifth* modality of natural selection is partnership within the species. This could explain the origin of multicellularity. Traits are transmitted to the progeny – to a wide extend – through the transmission of genetic material. Any phenotypic trait inducing a behavior which increases the transmission of the ► **genotype** coding for it will increase in frequency within a group of individuals. Consequently, it has been shown that cooperation between individuals increases with the genetic relatedness of the individuals. The different cells composing a multicellular organism are genetically identical – we all are clones from the egg from which we were issued. Thus, in sexually reproducing multicellular eukaryotes, selection has produced a developmental system in which most of our cells will not reproduce in the long run because they die with the organism (the somatic cells constituting our body) while only a small part of the individual's cells, the sexual (or germinal) cells will survive through producing offspring. From an evolutionary perspective, the fact that one cell or another within the organism produces a progeny makes no difference. Indeed, there can be competition among cells within an organism, but since only the germinal cells produce progeny, this process will not influence directly the hereditary make-up of the next generation. It can, however, be important in the determination of the success of the individuals in terms of survival or reproduction. For instance, if some cells behave independently from the others a cancer arises, with potentially immortal cell lineages but resulting in the death of the organism.

The same reasoning discussed in the above paragraph can easily explain parental care, since the hereditary traits of the parents will reproduce through the success of their progeny. It is interesting to note that in most species, the genetic relatedness between parents and offspring and between siblings is equal. Consequently, in several groups of organisms (termites, mole rats), the individuals raise their sibs instead of producing their own progeny. In some species (insects hymenoptera including bees, ants, wasps, etc.) however, the genetic relatedness is greater between

sisters than between a mother and her progeny. Hymenoptera are thus, not surprisingly, composed of a very high proportion of social species where most individuals raise their sisters and do not produce any progeny on their own. The family is thus a unit of selection as well as the individual.

Higher levels of selection also exist, but heated debates have been maintained concerning its application at the population level. One could think that populations that act in a coordinated manner better face the changes of threats of the environment than those that do not act so. Populations that protect their young can better transmit their traits to the offspring than those that do not. Populations that are more cohesive through help provided to the older or the weaker, through compassion, better face environmental changes. But theoretical models have shown that, because individuals can migrate from one population to another, this process can only act in very particular cases. Indeed, imagine a population of animals where everyone helps the others. If a migrant from a population where this trait does not exist arrives, he will benefit from the help without paying the cost of helping the others. This issue is still debated.

Selection at the family level or at higher levels can be considered as providing an insight into the natural origin of love, mutual help, compassion, and moral rules, given that such behaviors are transmitted to the next generation, whatever the nature of the transmission. Although it is too often forgotten, Darwin also wrote almost an entire book (Darwin 1871) about this topic. The ways by which our versions of our traits can be better spread through generations are diverse and we should not reduce natural selection to a “struggle for life” understood as a competition among individuals. This probably does not reflect the main factors by which natural selection plays, and this surely does not reflect the richness of Darwin’s thinking and contemporary evolutionary thought.

When considering a structure in an organism, we must be careful when evoking adaptation right away. Indeed organisms as wholes are compromises among traits. All traits are not under the same selective regime and “conflicts” occur. As discussed above, there is no “optimal organism”

to be understood as “perfect organism.” Perfection is not a scientific concept. Above all, the trait considered may not be present for direct selective reasons, but the by-product of a selection of another trait of the same organism (see above). The side effect is obtained through chemical or physical constraints of organism construction as consequences of a selection at another level or trait. But there is another reason for adaptation and side effects for a trait to be present: history. A trait can be present as heritage or “frozen accident” that has never been counter-selected. The pathway of our phrenic nerve is an example. That nerve connects the diaphragm to our spinal cord. The pathway is not the shortest possible. It passes through the thoracic cage, the neck and connects the spinal cord at the level of the first cervical vertebra. This long nerve is sometimes irritated, provoking hiccup. That pathway is a heritage of the ancient times, similar to the pathway of the homologous nerve in teleosts (modern fish) that starts under the skull and innervates some muscular blocks of the branchial basket situated just underneath. With the rise of tetrapods (animals with limbs) some 360 Ma ago, the neck separated the muscular blocks from the skull and throughout evolution the length of the nerve increased. It is easy to understand that the position where the nerve is getting inserted in the spinal cord is more anatomically constrained than the progressive lengthening of the nerve as the muscular block it serves is getting farther from the neck. The result is far from optimal but the interaction between selection and historical constraints have made it that way; one of the effects of the above cited “evolutionary tinkering.”

Evolution: Structures and History

The processes described above explain why generations flow and change through time. That flow of generations is genealogy. A genealogy is a network exhibiting ancestor-descendant relationships between individuals. In the theoretical scheme those relationships are among virtual individuals. In the empirical field those relationships are not accessible – except in the framework of a few generations – because ancestors have definitively disappeared. That flow of generations is

sometimes interrupted by extinctions, sometimes divided by obstacles. Obstacles can be mountains (case of the domestic mice in the Madeira Islands), chromosomal changes, pheromone changes, behavioral changes, etc. For a while, members of the genealogy of each part cannot meet and give rise to offspring. If the obstacle stays for long enough, alterations are going to produce divergence. Divergence can be strong enough to lead, sooner or later, to the impossibility for the two sets to give rise again to offspring. The genealogy is a continuous flow of changing individuals through times; at a small scale it is a network but at a larger scale there are diverging branches (we will see later on that there can be connections among those branches under certain circumstances). Now we have to manage another problem: we cannot speak about living things by giving a surname to each individual we meet. We need names at wider scales. We use these branches to give names to sets of individuals that are able together to give rise to offspring. These sets are called species. The “concept” of species is more complex than it seems and an important literature has been produced concerning it. Species has a definition: by convention, a species is a set of individuals collectively able to give rise to offspring, delimited from one point of divergence in the genealogy to the next point of divergence. In other words, a species is an inter-node in the theoretical genealogical tree of life. A species seems to be real in synchrony but is just conventional in diachrony (i.e., considered through a significant time span): today we know that cats do not make babies with dogs, but by considering the depth of times the theoretical genealogy does connect them and an arbitrary limit must be set somewhere. Species is therefore defined as a convention of language mapped onto a theoretical genealogical continuum. Note that branches or the tree of life can go extinct, or expand by producing new branches. There is thus a selection at this level, but it can only act by sorting out those lineages which do possess characteristics making them sustainable. These characteristics result from the processes described above. Natural selection in its usual sense is about the relative success of a given variation possessed by

individuals, not about the relative success of species. Natural selection can thus be seen as producing “locally optimal” organisms in terms of survival, or reproduction, or of transmission of their hereditary material, not in terms of survival of the species.

Species definition should not be confused with criteria of assignment – both having been too often confused into the single term of “species concept.” When we find an individual organism and we do not know *what it is*, we have criteria to assign the individual to an already known species: similarity (most often), interbreeding, and fertile offspring. Note that sex, seen as gene exchange between two individuals, exists in all groups of organisms including Bacteria and Archaea so that, even if the concept is less clear in some groups, it is still possible to recognize lineages which can, or cannot, mix their hereditary material.

Today we see sets of living beings that are separated by the impossibility of producing offspring: in the history of biology species have often been considered as real. The general theory predicts that we must consider in the deep times that these sets are connected to each other: their members do not produce offspring together but they should have done it in the past. This will be useful to reconstruct degrees of kinship among a given set of individuals. A cat has hair and a dog has hair. Why do they have hair? Is it because they live here under this climate? No: the white bear and the giraffe have hair and they do not live here. Do they have hair because they produce offspring together? No: everyone knows that dogs and cats, together, do not produce offspring. But there has been a time when they did it. The answer is in the past. Hair must have been inherited from common ancestors. By comparing organs, shape, metabolism, DNA sequences, whatever feature that can be recognized as *the same* in several individuals of different species, it can be interpreted as a sign of common ancestry. By comparing many features, a tree can be reconstructed, showing degrees in sharing features. Such a tree shows “who shares what with whom.” It is not a genealogy because there are no ancestor-descendant relationships. When such a tree is read with the theory of evolution in mind,

it becomes a ► **phylogeny**, a tree expressing “who is more closely related to who than others.”

A phylogeny does not express ancestor-descendant relationships between the actual individuals we have at hand, but expresses relative degrees of relationships among them. There can be ancestors in a phylogeny, but they are virtual. This is also true for fossils. Within a phylogeny, fossils of extinct species are treated like we treat extant species. They are just a collection of features gathered in a past organism. Fossils are at the tip of branches just like extant organisms. A given fossil can be the ancestor of some part of today's ► **biodiversity**, but we have no empirical mean to approach that kind of relationships. Modern phylogeny is not practiced anymore in terms of “who is descending from whom” but in terms of “who is closely related to whom,” which is more empirically powerful. Phylogenies are used in a wide variety of scientific investigations. Among them are classifications in natural history. Classifications are conventional and classification is the construction of a concept under the form of a virtual box. Here outside there is no “bird.” Here outside there are only individuals. “Bird” is a name associated with a box in my mind, gathering millions of individuals, themselves being gathered in some 10,000 species (themselves gathered in hundreds of genera, etc.). There are reasons why we created that box: a classification reflects properties of organisms we decided to point out. Did we decide to put all these species in a same box because they are good to eat? Because they are beautiful? Because they do the same things in their environment? Because they share the same features? A “good” or “efficient” classification is the one that is self-consistent, i.e., that is successful in organizing things according to the criteria we set. Today, systematists classify living organisms together because they do share features in common. The feature must define the group and must not be present at the same time outside the group. Because sharing features among species is interpreted by the theory of evolution as common ancestry, our classifications by shared features will be naturally extracted from phylogenies. A virtual “box” or “group” containing real organisms is a taxon. By mapping our boxes onto nodes

of a phylogeny, we produce complete taxa, i.e., taxa that contain one ancestor and all its known descendants. This is what we call monophyletic groups. In modern systematics – science of classifications – classification of organisms is related to the theory of evolution by the fact that the only valid groups are monophyletic groups.

The “tree of life” is a genealogical metaphor. We will never have the full genealogy of life, just because ancestors have disappeared. But a theoretical scheme of genealogy is required by scientific evolutionary thinking. The shape of that theoretical tree is changing. Divergences of branches are best constrained for most of the animals; however for other eukaryotes, bacteria, or archaea there can be exchange of material among well separated branches of the genealogy. They are horizontal (also called lateral) transfers of genetic material. In bacteria it can be so powerful that we are not sure that the shape of the tree is still the best scheme as a theoretical framework. Another phenomenon we must be careful about is multiple symbioses. When partners of a symbiosis are associated together for long enough, phylogenies reconstructed from each partner are expected to be the same. This is why we use mitochondrial DNA to trace the phylogeny of eukaryotes. But when associations are recent, genetic traces of kinship can be different for each of the partners.

Applications

Evolution Exported

The discovery and understanding of evolution has had a number of consequences in the thought of our societies. It has changed the perception of the world in many respects, influenced a number of different scientific fields, and even been at the origin of new technologies. The fields where evolution was exported are of two kinds. The first one is philosophical and sociological, i.e., outside scientific activity *sensu stricto*. It concerns philosophy, eugenics, and social Darwinism. The second field is purely scientific: evolutionary thought was exported into already developed scientific fields where it was initially absent. This concerns evolutionary psychology, Darwinian medicine,

cellular Darwinism, biochemistry, neural Darwinism, and genetic algorithms in computer sciences. It would be too long to develop these fields here but it is certainly necessary to give some insights into some of them.

From a philosophical point of view, once it is recognized that all living organisms are the result of a natural process, the perception of Nature (including human nature) is profoundly influenced. One of the major changes is that the fact that something exists does not anymore indicate that it is good (because it is the will of the Creator). The “Natural theology,” developed before Darwin (and which he was extensively taught), loses its justification. As Thomas Huxley (zoologist, friend of Darwin) stated, “Nature is neither moral nor immoral, but non-moral.” At first sight, there are thus no moral rules to be found in nature. However, since we are issued from an evolutionary process, the sense of justice, equity, and help could have something to do with the way the human lineage has evolved: there is a natural origin of our moral rules, a fact that is perceived as contradicting their presumably transcendental origin. Philosophical debates about these points have been going on for a century and a half and we shall not enter them here. Science is a collective activity whose first aim is just to rationally explain phenomena and objects of the real world. As such it has no program to contradict or confirm any theological or moral statement.

From a social point of view, the Darwinian theory, when fused with ► [genetics](#) under the name “NeoDarwinism,” was first applied to the human species. In the dark years following the 1929 economic crisis, the idea that the wonderful social and intellectual qualities or the “race” were due to natural selection led the scientific community to declare that there was a danger of degeneration due to the social laws adopted during the nineteenth century. The mix of political, sociological, and scientific considerations led to the birth of an applied science: eugenics. It developed and was strongly supported by the scientific community. In the USA and in Scandinavian countries, thousands of people were sterilized in order to prevent their genes from spreading. The Nazi

government in Germany used this theory to sterilize hundreds of thousands of people. These practices disappeared more or less slowly after Nuremberg. Another social application was more economic, it was called “social Darwinism” in 1880 by Emile Gautier, a French journalist referring to the political philosophy of Herbert Spencer. It proposed the idea that the social system should respect the principle of selection and let the best succeed and the others remain desperately poor in order to respect the laws of nature. Note that, among the various modalities mentioned above by which natural selection can play, Spencer considered only inter-individual competition. This theory is still supported among the theoreticians of neo-liberal economy. Darwin himself never took a position in favor of Spencer’s ideas. Indeed, Darwin’s personal writings show that his political ideas were rather different. On the left side of the political continuum, Kropotkin (1902) also referred to Darwin’s scientific writings when he tried to justify the naturalness of mutual help in human societies. It is important to point out that in either case we have an ideological work at play, picking up into science what is interesting for socio-political purposes. These intellectual by-products are not born by the sole will of the scientific community trying to explain the natural world.

On a more positive side, in the second category of fields that have imported the idea of evolution, the modern theory of evolution can help us understand psychology and the health questions in humans; this has led to the development of evolutionary medicine and psychology. Moreover, the Darwinian concept of variation selection has been imported into robotics, evolutionary algorithms, protein engineering, linguistics, biochemistry, neurosciences, cellular biology, etc. Such fecundity leads to the question of whether, outside its initial field, the use of the word “evolution” should be restricted to the process of variation of entities and selection by their environment, or the word should still be used in the wider vernacular sense of “a story to tell about change.” In the second sense there is no doubt that the word “evolution” can be used to mean the change of our Universe and all objects it contains from

galaxies to isolated molecules. In the first – more restrictive sense – applying the word evolution in the field of astronomy implies the identification of extraterrestrial objects susceptible to variation and the transfer of structure to similar entities, a transfer subject to environmental conditions. Thus, this process has not been used to describe the change of most of the large-scale objects we find in the Universe. However the word “evolution” has been used to describe changes in macromolecules that could be present in meteorites or planets, like amino acids or nucleotide polymers. Biological macromolecules were, whatever the ways by which they transfer their variations in sequence or conformation to others, probably the very first step of (precellular) evolution in the restrictive sense. As at least small precursors of the macromolecules are present in our extraterrestrial Universe, “evolution” is a rightful and suggestive concept in astrobiology.

Evolution Everyday

Evolution is not only a matter of fossils or DNA sequences. Evolution is needed to feed the entire human kind. There would be no agriculture without evolution. Artificial selection helped us to survive by domesticating various animals and plants. Often, one species has yielded very different varieties. The sole species *Brassica oleracea* yielded cabbage, broccoli, cauliflower, Brussels sprouts, and flowering kale. The different breeds of dogs (the species *Canis lupus familiaris*) differ much more in morphology and behavior than do other mammalian species. This is also evolution: just artificial selection among variants that humans used to produce differential demographic success in their offspring.

Evolution shapes medicine. A well-known example is the rapid spread of antibiotic resistance among different strains or species of bacteria by ► [lateral gene transfer](#). It is produced by the interchange of fragments of DNA (called plasmids) coding for proteins, able to degrade an antibiotic used in the clinical setting. The plasmid that confers the antibiotic-resistant ► [phenotype](#) in the recipient bacteria will be inherited by the progeny, allowing the resistant cells to evolve in the presence of such a selective

pressure. A second example: when people infected by the human immunodeficiency ► [virus](#) (HIV) are treated with antiviral drugs, the population of viruses that infects them evolves multiple amino acid substitutions that confer drug resistance in few months. As a consequence of HIV evolution, the antiviral drug combination must be changed.

Usually, evolution is not directly accessible to our senses, since large animals have long generation times and require very long periods to exhibit spectacular changes or speciation events. In turn, organisms with very short generation times, such as *Escherichia coli* and other bacteria, evolve very fast but we cannot see them with our sole eyes. Nevertheless, the evolution of fast-growing viruses or bacteria is easily monitored in the lab. Additionally, thanks to the advances in molecular biology, in vitro evolution is currently used to mimic and speed up the evolutionary processes at the molecular level.

Last but not least, evolution does not mean nor justify anything in terms of political or moral issues. Evolution is just the scientific approach to understand the origin of living beings and their changes through time. The approach uses amoral procedures, and our moral considerations do not have to be transferred to the living world (and reciprocally). Each time that such a transfer occurred along the history of our evolutionary sciences, it was a source of obstacles. Moral and political issues must be managed in the philosophical and political realms that surround scientific activity. They can give directions to research; however, scientific reasoning itself must stay out of these constraints.

[Prebiotic chemistry](#)

Definition

Chemical evolution refers to the suite of natural reactions that led to the first living systems from abiotically synthesized molecules on the primitive Earth. Since this was a historical process and we have no relics of the compounds formed in this process, chemists can only model chemical evolution by running experiments, chemical reconstructions also known as prebiotic chemistry.

Overview

Although primitive life is generally believed to have been organic, that is, based on ► [carbon chemistry](#), the precise sequence of steps that allowed for the formation of living systems from abiotic chemistry remains poorly constrained and somewhat speculative. Chemical evolution is the study of the processes that led from simple molecules to biochemistry.

There are presently numerous scenarios for this process which scientists consider plausible. Among them is the idea of a genetic mineral material presenting suitable properties such as the ability to store and replicate information (Cairns-Smith 1982). Another hypothesis favors a heterotrophic origin of life in a ► [“primordial soup”](#), involving self-assembling, preformed carbon-based molecules. An autotrophic origin of life via direct reduction of carbon oxides in a “metabolism-first” scenario has also been proposed (Wächtershäuser 2007).

While it is clear that all contemporary life shares a common heritage, it is possible that there were earlier, more primitive states that life evolved through which might have borne little resemblance to modern biochemistry. Some believe that primitive life emerged as a cell-like system requiring at least pre-RNA molecules capable of storing and transferring the information needed for reproduction, pre-enzymes providing

the basic chemical work, and pre-membranes able to isolate the system from the aqueous environment. Since RNA has been shown to be able to act as an information molecule and also as a catalytic molecule, RNA has been considered as a candidate for the first living system that preceded the cellular world. The spontaneous organization of amphiphilic molecules to form vesicles has also been postulated as the first step toward the origin of life (Morowitz 1992). Chemists are also tempted to consider that primitive self-replicating systems depended on simple autocatalytic molecules adsorbed on solid surfaces, which could solve some of the problems of the likely high dilution of organics in the primitive oceans.

Definition

In vitro evolution is an experimental method that allows the screening of large random-sequence libraries of nucleic acids – ► [RNA](#) or ► [DNA](#) – for a specific function, such as catalysis or binding. In vitro evolution experiments have led to the selection of novel or improved RNA enzymes, called ► [ribozymes](#), as well as artificial DNA enzymes – DNAzymes or deoxyribozymes – and target-binding nucleic acid molecules, ► [aptamers](#). The iterative in vitro process involves serial cycles of amplification and selection of the functional nucleic acid until the desired activity is reached. The outcome of directed evolution can be monitored through the analysis of the genotype and phenotype of the evolved molecules.

History

The first experiments aimed at determining if Darwinian evolution was possible in cell-free systems involved the in vitro replication of the RNA genome of the bacteriophage Q β – a ► [virus](#) that infects *Escherichia coli* – by the viral RNA replicase protein. Serial dilution experiments allowed the transfer of an aliquot of the replication mixture into a new reaction tube containing fresh enzyme and RNA monomers. The inherent mutation rate of the viral polymerase ensured genetic variation during the experiment, and the ► [phenotype](#) under selective pressure was the replication speed of the RNA genome. After several serial transfers, the Q β genome evolved by deleting sequences not required for its recognition by the polymerase, thus shortening the replication time (Mills et al. 1967).

A quarter century later, the availability of reverse transcriptase enzyme – RT, which catalyzes the conversion of RNA into DNA – and PCR technology, as well as the possibility to chemically synthesize nucleic acid pools of random sequence, opened a new era in in vitro evolution experiments. This field was also reinforced by the discovery of natural ► [ribozymes](#), what underlined the functional capabilities of RNA and its hypothesized key role in pre-cellular evolution. By 1990, directed evolution allowed the – artificial – selection of functional RNA molecules from random pools in two independent experiments that used the ability of RNA to bind a target molecule as the selective pressure. The stepwise process of amplification-selection was termed “Systematic Evolution of Ligands by Exponential Enrichment” or SELEX (Tuerk and Gold [1990](#)), and the term “aptamer” was coined to denote the in vitro evolved, target-binding RNA (Ellington and Szostak [1990](#)).

The next milestone in experimental cell-free evolution was the development of a system for continuous in vitro evolution of nucleic acids. In contrast to stepwise in vitro evolution, it combined the processes of selection, amplification, and genetic diversification within the same reaction mixture, thus allowing the continuous directed evolution of ribozymes (Wright and Joyce [1997](#)). In parallel, a new method termed “mRNA display” was set up for the in vitro selection of peptides and proteins (Roberts and Szostak [1997](#)).

Overview

The starting point of a stepwise in vitro evolution experiment is a large pool of nucleic acid molecules, in general, 10^{12} – 10^{16} , with a central region of random or mutagenized sequence, usually 20–100 nt long, flanked by two primer-binding sites of defined sequence. The successive amplification-selection rounds increase the ratio of active:inactive RNA – or DNA – and the pool finally becomes dominated by molecules with the desired ► [phenotype](#). Within each round, RNA amplification involves successive steps of reverse

transcription, PCR amplification, and ► [transcription](#). ► [Selection](#) is introduced by choosing for the next round only the nucleic acid molecules able to bind the target – aptamers – or to perform the desired activity – ribozymes – while non-functional molecules within the pool are discarded. The whole cell-free process occurs in vitro, and all the experimental variables can be controlled and fine-tuned. In vitro evolution can be distinguished from in vitro selection in that the former includes a continuous introduction of genetic variation in the molecular population, through mutation – usually, by error-prone PCR – and/or recombination (Wilson and Szostak [1999](#); Joyce [2004](#)).

In vitro evolution and in vitro selection have been used to obtain artificial nucleic acid enzymes and to engineer natural ribozymes to expand or improve their current functionality. The unveiled functional plasticity of RNA has increased the plausibility of the ► [RNA World](#) hypothesis for the origin and early evolution of life (Joyce and Orgel [2006](#)). In parallel, directed evolution of nucleic acids has generated new families of aptamers with diagnostic and therapeutic applications (Klussmann [2006](#)). Microfluidic chip technology and computer-assisted control have been incorporated to the biochemical process in order to automate the system and to monitor in real time the population size, its composition, and the performance of the evolved molecules (Paegel and Joyce [2008](#)).

Definition

Molecular evolution deals with the application of knowledge from biophysics, biochemistry, and molecular biology to biological evolution with the focus on understanding evolutionary phenomena at the molecular level. Two branches of molecular evolution are established fields of research: (1) reconstruction of phylogenetic trees by comparing genomic DNA sequences and (2) modeling evolution in vitro and in silico (i.e., by computer simulation), using simple models like populations of RNA molecules, simple viruses, or bacteria.

History

Molecular evolution originated from the vision of an evolutionary molecular clock by Linus Pauling and Emile Zuckerkandl in 1962 (Morgan 1998). Reconstruction of phylogenetic or evolutionary trees by comparison of biomolecular sequences became an established method through the works of Walter Fitch, Emanuel Margoliash, and Margaret Dayhoff in the 1960s, and the evolutionary clock (Kumar 2005) became an established tool in evolution research for dating speciation events. In vitro evolution of RNA molecules from bacteriophages was initiated by Sol Spiegelman in the 1960s (Spiegelman 1971). He showed that Darwinian evolution occurs in cell-free systems. At the same time, Manfred Eigen developed a kinetic theory of evolution at the molecular level (Eigen 1971). Since 20 years, molecular evolution has been applied to the evolutionary design of molecules with predefined properties and given rise to a new branch of biotechnology.

Overview

Evolution is based on the interplay of reproduction (providing the basis for inheritance, either by variation or ► [mutation](#) as a result of imperfect copying or recombination of genetic modules) and selection (choosing from the phenotypes present in the population). Insights into the molecular

machinery of life reveal the specific chemistry of reproduction initiated by replication of a nucleic acid molecule – DNA, or rarely RNA – which carries the genetic information in the form of a one-dimensional string of digits. Mutation occurs in three different forms: (1) single nucleotide incorporation errors commonly called point mutations, (2) insertions, when a part of the sequence is copied twice or several times, and (3) deletions, when a part of the sequence is missing in the copy. The unfolding of the genetic information, the ► **genotype**, or the genome, yielding the ► **phenotype**, is the key to understanding evolution, because it creates the repertoire upon which selection operates. The genotype-phenotype map is the source of complexity and varies from sequence-structure relations for in vitro evolution of molecules to the entire process of development leading from the fertilized egg to the adult organism in case of higher organisms.

Every organism carries information on its own history in the form of the DNA or RNA sequence that originates through mutation events. Molecular phylogenetics reconstructs the tree of life from present-day sequences of species (Graur and Li 2000) in which the proper alignment of sequences is an important part of the procedure (Mount

2004). Comparing sequences from vertebrates reveals the molecular clock of evolution (Morgan 1998; Kumar 2005; Takahata 2007), which implies that the number of single point mutations per nucleotide site and time is approximately constant for a given protein molecule. Further investigations have shown substantial vagaries of the clock, but in the age of genomics, the molecular clock turned out to be a valuable device for dating historical events. The last 40 years have seen a heavy debate between selectionists and neutralists about the role of mutations that have no influence on the ► **fitness** values of their carriers. Data on the evolution of entire genomes are ending this controversy through the discovery of new mechanisms dominating genome evolution (Nei 2005).

In the language of chemical kinetics, the evolution of molecules through correct replication and mutation under controlled conditions (Fig. 1) is cast into a first-order differential equation:

$$\frac{dx_j}{dt} = \sum_{i=1}^n Q_{ji} f_i x_i - x_j \varphi(t) \quad \text{with} \quad (1)$$

$$\varphi(t) = \sum_{i=1}^n f_i x_i \quad \text{and} \quad \sum_{i=1}^n x_i = 1.$$

Evolution, Molecular, Fig. 1 An example of a reaction mechanism for replication and mutation according to Eq. 1. An enzyme binds the template molecule (X_j) and the building blocks for polynucleotide synthesis (M). Correct replication and mutation are parallel chemical reactions with a rate parameter f_j , individual reaction channels lead to correct replication with frequency Q_{jj} and to a variety of

mutants with frequency Q_{ji} with $i \neq j$. Stable inheritance requires $Q_{jj} > Q_{ji}$ and sufficiently large (see the error-threshold shown in Fig. 2). Since every replication product is either correct or a mutant, a conservation relation $\sum_i Q_{ji} = 1$ holds. After the replication is completed both polynucleotide molecules, template and copy, are released from the enzyme, which is free for the next replication round

This equation describes the changes in genotype distribution of a population that consists of n different genotypes $X_1, X_2, \dots, X_n$. The variables are relative concentrations: $x_j = N_j / \sum_{i=1}^n N_i$ with $N_i = [X_i]$ being the number of molecules of type X_i . The parameters in Eq. 1 are (1) the replication rate parameters or fitness values for the individual genotypes, f_i , and (2) the mutation frequencies, Q_{ji} representing the frequency at which X_j is obtained as an error copy of the template X_i . The first term in Eq. 1 describes the production of X_j either as a correct copy, $Q_{jj}f_jx_j$, or as an error copy from another genotype X_i , $\sum_{i=1, i \neq j}^n Q_{ji} f_i x_i$. The second term, $\varphi(t)$, is a flux compensating for the excess production of genotypes. Mathematical analysis of the solutions of Eq. 1, which are obtained by integrating factor transformation and solution of an $n \times n$ eigenvalue problem (Eigen et al. 1989), yields two results that are relevant for biology:

1. The long time or stationary solution is given by the largest eigenvector ξ_0 of the matrix $W = QF$, where $Q = \{Q_{ij}; i, j = 1, \dots, n\}$ and $F = \{F_{ij} = f_i \delta_{ij}; i, j = 1, \dots, n\}$, the diagonal matrix of fitness values (δ_{ij} is Kronecker's symbol, $\delta_{ij} = 1$ if and only if $i = j$ and 0 otherwise). All elements of ξ_0 are positive by Perron-Frobenius theorem and hence no genotype will vanish. The largest eigenvalue λ_0 is nondegenerate and hence the result of the mutation selection process is unique. No matter what the initial conditions were, the population will converge toward a unique distribution of genotypes called *quasispecies* (Eigen and Schuster 1979), which consists of a fittest genotype, the *master sequence* X_m , and its mutant cloud.
2. Consideration of quasispecies as a function of the mutation rate p , $\xi_0(p)$, reveals a critical mutation rate p_{cr} at which the genotype distribution changes abruptly from the quasispecies centered around the master sequence into the uniform distribution (Fig. 2). Neglecting mutational backflow from mutants to the master sequence, the critical mutation rate is obtained as

$$\begin{aligned} p_{cr} &= 1 - \sigma_m^{-1/\ell} \quad \text{with} \\ \sigma_m &= \frac{f_m}{\bar{f}_{-m}} \quad \text{and} \\ \bar{f}_{-m} &= \frac{1}{1 - x_m} \sum_{i=1, i \neq m}^n f_i x_i \end{aligned} \quad (2)$$

In this equation, the chain length of the genotype is denoted by ℓ , x_m is the relative concentration of the master sequence, σ_m is the superiority of the master sequence, and $\bar{f}_{-m}$ is the mean fitness of the population except the master sequence. Equation 2 has two important consequences: It defines (1) a maximal chain length for constant replication accuracy $(1 - p)$, $\ell_{\max} \approx \ln \sigma_m / p$, and (2) a maximal error rate for constant chain length ℓ , $p_{\max} \approx \ln \sigma_m / \ell$. Both limitations have immediate consequences in biology: (1) In classes of organisms, the spontaneous mutation rates determined by the accuracy of the replication mechanism are inversely proportional to genome lengths (Drake et al. 1998; Gago et al. 2009), and (2) for RNA virus replication, which occurs at mutation rates as close to the error threshold as possible in order to guarantee maximal variability in fighting the defense system of the host, a drug-induced increase of the mutation rate can drive the population into extinction (lethal mutagenesis; Domingo et al. 2008).

Molecular evolution experiments starting with the seminal work of Sol Spiegelman (Spiegelman 1971) and continued by Christof Biebricher, Jack Szostak, Gerald Joyce, and others (Watts and Schwarz 1997; Joyce 2004, 2007) represent experimental realizations of the theory. Evolution experiments under controlled conditions were also carried out with bacteria, and radical innovations induced by mutations were interpreted successfully at the molecule level (Blount et al. 2008). The molecular approach to evolution is completed by introducing a relation between genotypes and phenotypes in the form of a mapping or fitness landscape, which in the simplest system, in vitro evolution of RNA, deals with RNA sequences and structures (Schuster 2003, 2006). Evolutionary phenomena, for example,

Evolution, Molecular, Fig. 2 The accuracy limit for replication. The two plots show solution curves of Eq. 1 as functions of the mutation rate p . In order to illustrate the phase transition-like change in the mutant distribution at the error threshold (2) the relative concentration of error classes $y_k(p)$ are plotted against p : $y_0(p)$ represents the concentration of the master sequence, $y_1(p)$ is the sum of the concentrations of all one-error mutants, $y_2(p)$ is the sum of the concentrations of all two-error mutants, $y_3(p)$ is

the sum of the concentrations of all three-error mutants, etc., and in general $y_k(p)$ is the sum of the concentrations of all k -error mutants. At the error-threshold the quasispecies changes abruptly into the uniform distribution, and the concentrations of the mutant classes become equal to the binomial coefficients. The lower part of the figure represents an enlargement of the curves around the error-threshold. Parameters used in the calculations: chain length $\ell = 100$, fitness values $f_0 = 10, f_n = 1$ for all $n \neq 0$

the existence of error thresholds, are highly sensitive to the fitness landscape and commonly applied. Oversimplified models based on the unrealistic assumptions that mutations contribute to fitness additively or in a multiplicative way give wrong results (Phillipson and Schuster 2009). Neutrality is a fundamental property of realistic fitness landscape, and neutral evolution (Kimura 1983) in parts of the sequence space is indispensable for the success of the Darwinian mechanism (Schuster 2006).

Molecular kinetics of evolution and most of population genetics are based on modeling by means of differential equations. The limitations of this approach primarily come from small particle numbers – every mutant has to start from a single copy; uniform distributions are completely unrealistic since there are orders of magnitude less molecules in the population than possible genotypes. Proper stochastic treatments and computer simulations were performed, but a universal model of finite population size effects in evolution is not at hand.

Basic Methodology

The methodology of molecular evolution is shared with molecular genetics, genome research, population genetics, bioinformatics, and biochemical kinetics. Specific developments concern the construction of special flow reactors and other equipment for evolutionary biotechnology (Watts and Schwarz 1997).

Key Research Findings

The phylogenetic tree of conventional biology has been approved independently by molecular phylogenetics. The molecular clock of evolution yields a genetic measure of time. In vitro evolution has provided evidence that Darwinian evolution does not require reproduction at the cellular level. Quasispecies theory and existence of error thresholds for replication provide a solid theoretical basis for virus evolution at the molecular level.

Applications

In vitro evolution of molecules was applied to the design of molecules with predefined properties in biotechnology and became a popular tool for systematic evolution of ligands by exponential enrichment (SELEX[®], which is a registered trademark of the company Gilead Sciences, Foster City, CA). Examples are the evolutionary design of nucleic acid molecules (Joyce 2004; Klusmann 2006), proteins (Brakmann and Johnsson 2002; Jäckel et al. 2008), and synthetic compounds (Wrenn and Harbury 2007). Quasispecies theory and the concept of error propagation in successive replication gave rise to new antiviral strategies known as lethal mutagenesis (Domingo et al. 2008). Together with rational design, evolutionary biotechnology represents a core technique of synthetic biology.

Future Directions

The promising and challenging future program for molecular evolution is the integration of data from genomics and systems biology into the currently

used methods. Whereas phylogenetics on the whole genome level is more or less solved, upscaling of modeling evolution from RNA molecules and viruses to cells and organisms will require new experimental and computational tools. Learning how genotypes are mapped into phenotypes represents the key for understanding evolution at the molecular level.

Exergonic

Jacques Reisse

Université Libre de Bruxelles, Brussels, Belgium

Definition

The term exergonic refers to a chemical reaction that releases free energy as it proceeds. An exergonic reaction may also be ► [exothermic](#), but does not need to be (see ► [entropy](#)). An example of exergonic reaction is gasoline ► [oxidation](#) in the Earth's atmosphere; burning gasoline releases sufficient free energy (work) to propel a car.

It is important to make a clear distinction between thermodynamics and kinetics. A spontaneous reaction can be characterized by a rate so small that no change can be observed, as is the case with gasoline in the presence of oxygen at normal temperature. A temperature increase by a flame or spark is sufficient to initiate a combustion reaction which, being not only exergonic but also exothermic, then proceeds without any additional supply of heat. Many biochemical reactions are exergonic but extremely slow in the absence of a catalyst (for example an enzyme). In the presence of enzymes, however, the reactions proceed at an appreciable rate at low temperature.

Exobiologie Experiment

Michel Viso

Innovaxiom, Paris, CX, France

Definition

During the ► [CNES](#) sponsored mission “Perseus,” the experiment “exobiologie” was

flown in 1999 onboard the Russian MIR space station and exposed for 97 days outside the station (April 16–July 9). Samples containing chiral ► [amino acid](#) (► [leucine](#) and alpha-methyl leucine) and peptides (leucine-diketopiperazine and trileucine thioethylester), mixed or not with montmorillonite or meteoritic powder, were deposited on windows of magnesium fluoride and exposed directly to the solar UV flux. Spores of *Bacillus subtilis* mixed with meteoritic powder were also exposed in cooperation with the DLR. As references, duplicates of the samples were placed in the instrument but hidden from the solar light as ground-based experiment was conducted.

Analysis of the material after the flight did not reveal any racemization or polymerization of the amino acids but did provide information regarding photochemical pathways for the degradation of leucine and of the tripeptide. Very thin layers of inorganic material did not protect spores against the deleterious effects of energy-rich UV radiation in space to the expected amount. Surprisingly, self-formed layers of UV radiation inactivated spores serve as a UV shield by themselves. The

hypothetical interplanetary transfer of life by the transport of microorganisms inside rocks through the solar system cannot be excluded but requires the shielding of a substantial mass of inorganic substances (Rettberg et al. 2002; Fig. 1).

Definition

In geology, exogenous (from Greek *exo*, outside) refers to all the geodynamic processes that are produced on the surface of the Earth (and other planets). Weathering, erosion, transport, and sedimentation are the main exogenous processes. The result of these processes is the formation of sediments and sedimentary rocks and the morphological transformation of the planetary landscape. The main source of energy is the Sun, its radiation leading to atmospheric heating, wind circulation, and climate changes. Internal heat of the planet can contribute in a very minor amount to exogenous processes.

Definition

ExoMars is a cooperative program of the ► [European Space Agency](#) (ESA) and the Russian Space Agency, Roscosmos, to develop and launch two missions.

The first ExoMars mission was launched on 14 March 2016 and arrived at the red planet on 19 October 2016. ExoMars 2016 included two elements: (1) the Trace Gas Orbiter (TGO), to study subsurface water and atmospheric trace gases with the goal to acquire information on possible ongoing biological or hydrothermal processes; and (2) Schiaparelli, a European Entry, Descent, and Landing (EDL) demonstrator equipped to perform measurements during descent and on the Martian surface. Schiaparelli was able to transmit much valuable information during EDL, but unfortunately the last phase of the sequence did not work and the lander crashed. After performing a series of atmospheric aerobraking passes lasting approximately 1 year, TGO reached its science orbit in early 2018 and began performing its science mission. TGO also provides data communication services for surface landers and rovers.

The second ExoMars mission will deliver two science elements to the Martian surface (see Fig. 1): (1) *Kazachok*, a surface platform (SP) instrumented to perform environmental and geophysics measurements; and (2) *Rosalind Franklin*, a 300-kg rover tasked with conducting a search for signs of life (Vago et al. 2017).

History

ExoMars was originally conceived as a rover mission carrying a drill capable to collect small samples from the subsurface and analyze them. The initial work aiming to define the scope of the rover mission and its payload started in 1996. A group of scientists was tasked by ESA to make recommendations for future search-for-life missions on Mars. Their findings were collected in the so-called ESA “Red Book” report of 1999. During 2001, the nascent ESA Aurora program for Solar System exploration decided to pursue the Mars exobiology rover concept. In 2003, ESA issued a call for instruments to be accommodated on the 2009 ExoMars rover. The ExoMars mission was approved in 2005. A last-minute request to add a lander station resulted in a more complicated mission concept,

ExoMars, Fig. 1 Artist depiction of rover and surface platform. (Credit: ESA/Mlabspace)

requiring a larger launcher, which could not be realized within the available budget. A number of studies were necessary to redefine the mission, and thus the launch date was postponed, first to 2011 and then to 2013. At the same time, NASA was experiencing cost overrun problems with their ► [Mars Science Laboratory \(MSL\)](#) mission that affected their capability to independently realize a mission in 2016. In the course of 2009, ESA and NASA decided that they could accomplish more by joining forces. A scenario was defined for an ESA-NASA joint program that had as ultimate goal the realization of an international ► [Mars Sample Return \(MSR\)](#) mission in the mid to late 2020s. Within this program, ESA and NASA defined the first two missions, in 2016 and 2018. In late 2011, budget constraints in the USA forced NASA to scale down its participation. ESA, NASA, and Roscosmos started a dialogue aiming to realize the program as a tripartite collaboration. However, in early 2012 NASA informed ESA and Roscosmos that they would not be able to contribute major elements. Following a program reassessment phase, in 2013 ESA and Roscosmos signed a cooperation agreement to work in partnership to develop and launch two ExoMars missions in 2016 and 2018. The first mission was launched in time. The second one

had to be postponed to 2022, initially due to implementation delays and later because of the COVID-19 pandemic crisis.

Overview

Establishing whether life ever existed, or is still active on Mars today, is one of the outstanding scientific questions of our time. The ExoMars program seeks to address this important scientific goal and to demonstrate key flight and in situ enabling technologies underpinning European and Russian ambitions for future exploration missions.

The ExoMars scientific objectives are the following:

- To search for signs of past and present life on Mars
- To investigate the water/geochemical environment as a function of depth in the shallow subsurface
- To study Martian atmospheric trace gases and their sources
- To characterize the surface environment

In support of these objectives, the following technologies will be achieved:

- Entry, Descent, and Landing (EDL) of a payload on the surface of Mars
- Surface mobility with a rover
- Access to the subsurface to acquire samples
- Sample acquisition, preparation, distribution, and analysis

The 2016 TGO includes two scientific instruments for the detection of atmospheric trace gases, the study of their temporal and spatial evolution, and the localization of their source regions (NOMAD and ACS). It also has a neutron detector for the mapping of shallow subsurface ice (FREND), and a color stereo camera (CaSSIS).

The ExoMars 2022 launch period opens on 20 September 2022 and extends until 1 October. The landing will take place on 10 June 2023.

Basic Methodology

The Surface platform (SP) will conduct environment and geophysics investigations for a nominal period of one Martian year. The large majority of the meteorological SP measurements will be periodic in nature, e.g., sample temperature and humidity at regular intervals throughout the day and seasons. Other measurements will be decided

on the basis of opportunity and resources. SP investigations can be programmed several sols in advance.

The nominal duration of the rover search-for-signs-of-life mission is 211 sols. In contrast to the SP, rover operations require twice-daily interactions with ground control. This is because precise knowledge of yesterday's results (e.g., rover final drive position) is needed to plan today's activities (e.g., obtaining a sample for analysis). Typically, the rover will be instructed using a morning satellite overflight and report back on an evening telecommunications pass.

After landing, once the SP and rover status have been stabilized (Fig. 2), the next important stage will be the descent of Rosalind Franklin onto the Martian surface. The rover will remain in the vicinity of the SP for a few weeks. The rover and SP can image each other, assist with commissioning activities, and conduct proximity science measurements. Once this proximity phase will have finished, the rover will drive off. The two surface elements will then begin their individual missions.

If life ever arose on the red planet, it probably did when Mars was wetter, sometime within the first billion years following planetary formation. Conditions then were similar to those when microbes gained a foothold on the young Earth.

ExoMars, Fig. 2 Artist view of mission after landing. (Credit: ESA/Mlabspace)

Both planets had the necessary environmental conditions and ingredients for life, namely, liquid water, carbon, and other essential elements, as well as a source of energy. Life could have arisen in suitable locations, such as in the vicinity of hydrothermal activity, where all requirements could have existed, even if the standing bodies of water were ice-covered. This marks Mars as a primary target for the search for signs of life in our Solar System.

The rover will use a drill to collect samples from outcrops and at depth. The drill can reach down to 2 m below the surface. Such depth range has never been probed on Mars before. ExoMars' subsurface sampling capability will provide the best chance yet to access and analyze sedimentary deposits, possibly containing molecular biosignatures, that may have been shielded from the ravages of ionizing radiation prevailing at the surface.

The rover's Pasteur payload includes the following: panoramic instruments (PanCam (Coates et al. 2017) wide-angle and high-resolution cameras; ISEM (Korablev et al. 2017), an infrared spectrometer; WISDOM (Ciarletti et al. 2017), a ground-penetrating radar; and ADRON (Mitrofanov et al. 2017), a neutron detector); a subsurface drill to acquire samples; contact instruments for studying rocks and collected material (CLUPI (Josset et al. 2017), a close-up imager; and Ma_MISS (De Sanctis et al. 2017), an infrared spectrometer in the drill head); a Sample Preparation and Distribution System (SPDS); the analytical laboratory, the latter including Micro-mega (Bibring et al. 2017), a visual and infrared imaging spectrometer; RLS (Rull et al. 2017), a Raman spectrometer; and MOMA (Goesmann et al. 2017), a Laser-Desorption, Thermal-Volatilization, Derivatization, Gas Chromatograph Mass Spectrometer (LD + Der-TV GCMS).

The ExoMars 2022 mission will land at Oxia Planum, an ancient location with strong potential for past habitability and for preserving physical and chemical biosignatures (as well as abiotic/prebiotic organics). Oxia Planum is situated on the eastern margin of the Chryse basin, along the Martian dichotomy border, and at the outlet of the Coogoon Valles system. The coordinates

for the nominal touchdown location are 18.159°N, 24.334°W. The approximately 100 km × 9 km dispersion ellipse lies in the lower part of a wide basin, where extensive exposures of Fe/Mg-phyllosilicates (>80% of the ellipse surface area) have been detected with OMEGA and CRISM hyperspectral and multi-spectral data. The Fe/Mg-rich clay detections are associated with early/middle- to late-Noachian layered rocks (with layering thickness ranging from a few meters to <1 m for several tens of meters). They may represent the southwestern expansion (lowest member) of the Mawrth Vallis clay-rich deposits, pointing to a geographically extended aqueous alteration environment, perhaps an ocean.

No previous mission will have landed at such an ancient location. The Oxia Planum clay deposits are dated at 4.1 Ga, from the epoch when Mars' surface was crisscrossed by plentiful liquid water systems. The oldest landing sites so far have been that of Perseverance (Jezero Crater, 3.8 Ga) and Curiosity (Gale Crater, 3.6 Ga).

In the case of a possible biosignature discovery, independent confirmation of the results will require more thorough analyses than can be performed by remote robotic means. The ExoMars 2022 mission will contribute to determining what types of samples we should return to Earth for further studies.

The Martian Environment and the Need for Subsurface Exploration

For organisms to have emerged and evolved, liquid water must have been present on Mars. Without it, most cellular metabolic processes would not be possible. In the absence of water, life either ceases or slips into a quiescent mode. Hence, the search for extinct or extant life automatically translates into a search for liquid water-rich environments, past or present.

The strategy to find traces of past biological activity rests on the assumption that any surviving signatures of interest will be preserved in the geological record, in the form of buried/encased remains, organic materials, and fossil communities. Because current Martian surface conditions

are hostile to most known organisms, when looking for signs of extant life, the search methodology must focus on investigations in protected niches: in the subsurface and within surface outcrops. Therefore, the same sampling device and instrumentation can adequately serve both types of studies.

The rover's surface mobility and the 2 m vertical reach of the drill are both crucial for the scientific success of the mission.

The ExoMars rover will search for two types of life-related signatures: morphological and chemical. This will be complemented by an accurate determination of the geological context. Morphological information related to biological processes may be preserved on the surface of rocks. Possible examples include the biomediated deposition of sediments, fossilized bacterial mats, stromatolite mounds, etc. Essential for these studies are mobility and an imaging system capable of covering from the meter scale down to submillimeter resolution (to discern microtextural information in rocks).

Effective chemical identification of biosignatures requires access to well-preserved organic molecules. Because the Martian atmosphere is more tenuous than Earth's, three important physical agents reach the surface of Mars with adverse effects for the long-term preservation of organic compounds: (1) The ultraviolet (UV) radiation dose is higher than on our planet and will quickly damage potential exposed organisms or biomolecules; (2) UV-induced photochemistry is responsible for the production of reactive oxidant species that, when activated, can also destroy organics; the diffusion of oxidants into the subsurface is not well characterized and constitutes an important measurement that the mission must perform; and (3) finally, ionizing radiation penetrates into the uppermost meters of the planet's subsurface. This causes a slow degradation process that, over many millions of years, can alter organic molecules beyond the detection sensitivity of analytical instruments. Please note that the ionizing radiation effects are depth dependent: The material closer to the surface is exposed to a higher dose than that buried deeper.

A major goal of ExoMars is to study ancient (older than 3.8 billion years) sedimentary rock

formations. However, the chemical record of early Martian life, if it ever existed, is likely to have escaped radiation and damage only if it is trapped in the subsurface for long periods. Studies show that a subsurface penetration in the range of 2 m is necessary to recover well-preserved organics from the very early history of Mars.

Additionally, it is essential to avoid loose dust deposits distributed by eolian transport. While driven by the wind, this material has been processed by UV radiation, ionizing radiation, and potential oxidants in the atmosphere and on the surface of Mars. Any organic biosignatures would be highly degraded in these samples.

For all the above reasons, the ExoMars drill will be able to penetrate and obtain samples from well-consolidated (hard) formations, at various depths, from 0 down to 2 m.

Key Research Findings

In spite of their sensitivity (1000 to 10,000 higher than that of instruments on previous missions), TGO observations using the NOMAD and ACS instruments have not detected atmospheric methane at the altitudes they can explore using the Sun occultation technique (typically between 5 and 25 km) down to a minimum detection limit of ~ 0.01 ppbv (Korablev et al. 2019). This is in contradiction with reports from Curiosity's team who claim to have measured in situ levels between 0.2 and 0.8 ppbv as continuous background and more during putative peak emissions. This difference remains to be explained.

Another important finding of TGO has been the role that atmospheric heating and subsequent inflation during large dust storms have on boosting atmospheric and especially water vapor escape (Vandaele et al. 2019; Fedorova et al. 2020).

The FREND neutron detector on TGO has discovered numerous areas of shallow buried water ice deposits (local regions with suppressed neutron flux that indicate the presence of considerable hydrogen) in the Mars tropical band (Malakhov et al. 2020). These permafrost oases

have water mass fractions varying between 30% and 100%.

The CaSSIS camera on TGO has obtained more than 20,000 color images of the Martian surface, many of which are stereo pairs.

Future Directions

TGO will continue its science and data relay mission. The next challenge is to launch, land, and perform ExoMars 2022. Beyond this, ESA and NASA are working on Mars Sample Return.

Exomoon

Nader Haghighipour

Institute for Astronomy, University of Hawaii-Manoa, Honolulu, HI, USA

Definition

An exomoon is a natural satellite (as opposed to an artificial satellite) of an extrasolar planet. In analogy to the solar system where many of the planets have moons around them, it is expected that extrasolar planets will host moons as well. No exomoon has yet been firmly discovered (as of 2021), as the detection of exomoons is a very complicated task with all current detection techniques.

In 2018, Teachey and Kipping announced the detection of a Neptune-size exomoon candidate around the giant planet Kepler-1625b. However, this discovery was challenged by several studies (e.g., Kreidberg et al. 2019) and the detection was not confirmed.

[Extrasolar planets detection and characterization](#)

Definition

An exoplanet, or extrasolar planet, is a planet in orbit around another star. The first of such objects was discovered in 1992 and about 5,200 exoplanets have been identified today (November 2021). Because an exoplanet's reflected visible light is (in the case of a system comparable to ours) $\sim 10^{-9}$ times weaker than the stellar flux, indirect methods such as Doppler velocimetry

(radial velocity technique) and transit photometry have first been used to detect these objects. Before the first discoveries in 1995, astrometry was tried without success, as the available instrumental means were not sensitive enough to detect such small motions. The velocimetry technique was later successfully used, and, since 1995, this has led to the discovery of about a thousand exoplanets. Since 2000, the transit photometry technique has been especially successful, in particular with the CoRoT space mission, launched in 2006, and even more with the Kepler space telescope which provided a very large amount of data. The number of planets detected by this method is close to 3500. Other methods have also been successful, in particular microlensing surveys, and, more recently, direct imaging (see ► [Direct-Imaging, Planets](#), and ► [Transiting Planets](#)).

History

The question of the plurality of worlds is probably as old as humanity. In Antiquity already, some philosophers suggested the possible existence of inhabited worlds outside the solar system. In the Middle Ages and later, the question was very much under debate among philosophers and scientists. Astronomical programs for detecting exoplanets started at the beginning of the twentieth century. Following the work of Friedrich Bessel (1784–1846) who had discovered a low-mass companion around Sirius, the ► [astrometry](#) technique was favored. In 1944, Piet Van de Kamp announced the discovery of a planet around Barnard's star. After many studies, it turned out that the apparent star motion was due to an artifact, caused by systematic instrumental errors. In the 1980s, astronomers came to the view that, in light of the performances of the available instruments, astrometric techniques were not sufficiently accurate for detecting exoplanets.

The first true exoplanet was discovered in 1992 around a pulsar, using the method called pulsar timing. Pulsars, first detected in 1967 by J. Bell and A. Hewish, are neutron stars, at the very last stage of their lifetime. These stars rotate extremely rapidly and have a very strong magnetic field. As a

result, they emit a periodic radio signal which can be detected from Earth. If a planet is present around the pulsar, it creates a perturbation in the radio signal. In the 1970s, several tentative detections were announced but none of them was confirmed until, in 1992, Alexander Wolszczan discovered the presence of two planets around the pulsar PSR1257 + 12; this object has an especially fast rotation period of 1.5 ms. Over 40 objects around pulsars have been detected since 1992. These first detected exoplanets have of course no resemblance at all with solar system planets and bear little interest for astrobiology (the intense and periodic radiation may not be favorable for life as we know it).

Still in the 1970s, astronomers started developing another indirect method, called velocimetry or radial velocity measurement. The idea is, like astrometry, to detect the motion of the star with respect to the center of mass of the system, but this time the velocity is measured using the Doppler technique. At the beginning of the 1980s, three teams were especially active in carrying out such long-term programs: M. Mayor for the Observatory of Geneva, the team led by G. Marcy and P. Butler in the USA, and the team led by G. Walker and B. Campbell in Canada. After over a decade with no result, the first discovery was announced in 1995 by M. Mayor and D. Queloz, using the 1.93 m telescope of Saint-Michel Observatory (Fig. 1). An exoplanet was detected around a solar-type star, 51 Pegasi. More surprisingly, the object was a giant exoplanet (with a mass at least half of Jupiter), orbiting at only 0.05 AU from its star, with a revolution period of only 4 days! This outstanding discovery was followed by many others. In 1996, G. Marcy announced the detection of two other exoplanets, around 47 UMa and 70 Vir. The following detections confirmed the strange nature of the exoplanets: most of them were ► [giant planets](#) orbiting in the close vicinity of their star. This situation was completely unexpected: at the time, the formation scenarios of the solar system suggested that planets, formed by the accretion of solid particles within the ► [protoplanetary disk](#), should be small and rocky objects near their star, and gas- or ice-giants at larger distances. The first implication of the discovery of extrasolar

Exoplanet, Detection, and Characterization, Fig. 1 The velocity curve of 51 Pegasi, measured by Mayor and Queloz (1995) at the Haute Provence Observatory. The sinusoidal shape of the curve is the signature of the presence of a planet which orbits the star at the same period. (After Ollivier et al. 2009)

planets was that indeed exoplanets do exist around solar-type stars, but their formation scenario – or at least their evolutive process – may be very different from that of the solar system.

The second major step in the exploration of exoplanets was the detection of planets by the method of transits. When a planet transit in front of its host star, the stellar flux slightly decreases, and this small variation may be detected using very stable photometry. The method has been used since the beginning of the twenty-first century, both from the ground and from space, and is responsible for the majority of exoplanet discoveries.

Overview

The main problem for detecting exoplanets is the huge contrast between the reflected planetary flux and the stellar flux, and the very small angular distance between the planet and its host star. As mentioned above, for a Jupiter-like planet located at 5 AU from a solar-type star, the flux contrast is

10^{-9} in visible light. As the planet is a cold object, the situation improves in the infrared with a contrast of about 10^{-6} at $10\text{ }\mu\text{m}$. For a star located at 10 pc for the Sun (a typical distance for a sample of nearby stars), the star-planet angular separation is 0.5 arcsec . With the present means, it is extremely difficult to obtain a direct image of a Jupiter-like planet around a solar-type star, even in the infrared.

Direct imaging can be considered for star-planet systems with a more favorable contrast and a larger separation. This implies looking for cooler and smaller stars, that is, M-type dwarfs, and large exoplanets far from their host stars, or highly luminous stars such as A stars and very large exoplanets at very large separation (e.g., tens of AU). The first direct image of an exoplanet was obtained by G. Chauvin and his team from the Observatoire de Grenoble (Fig. 2). The star, 2MASS1207, has a mass of 0.025 solar masses. Its planet, located at 55 AU from the host star, has a mass of five Jovian masses. The observation was performed in the near-infrared range at the **VLT**, using adaptive optics; the detection was made easier by the fact that the host star is a **brown dwarf**, much cooler than typical stars. This discovery was the first one of a promising research field.

Exoplanet, Detection, and Characterization, Fig. 2 The planetary system 2MASS1207 observed from the ground in the near-infrared range by the NACO instrument on the VLT (Chauvin et al. 2005). (Figure from ESO)

A more prominent and highly studied planetary system detected by direct imaging is the four-planet system of the A star HR 8799.

The Indirect Detection Techniques

Astrometry and Velocimetry

As mentioned above, both astrometry and velocimetry have been used for measuring the stellar motion around the center of mass of the system. In the case of the solar system, the motion induced on the Sun by Jupiter corresponds to a velocity of 12.5 m/s ; in the case of the Earth, it is only 9 cm/s . In the case of astrometry, as seen by the observer, the motion of the star is an ellipse, which becomes a line segment if the observer is located in the plane of the planetary system. In the case of velocimetry, the situation is reversed. The observer measures the projection of the stellar motion along the line of sight (called the radial velocity). As a result, the velocity curve is sinusoidal and maximal if the observer is in the plane of the system, but is zero if the observer is aligned with the rotation axis of the system. As the viewing angle of the system is unknown, only a lower limit of the planet's mass is retrieved, in addition to its period.

The detection of exoplanets by the astrometry method from the ground has been so far beyond instrumental capabilities. In the near future, it could become feasible from the ground for giant exoplanets with the interferometric instrument PRIMA at the VLTI. However, the main instrument for exoplanet detection is the Gaia astrometry space mission, launched by the European Space Agency in 2013, which should lead to the detection of a huge number of exoplanets, especially massive objects at large distances from their host stars.

As mentioned above, velocimetry has been the first tool of exoplanets' detection. The success of this method is due to the unexpected fact that massive objects are found very close to their stars, which is especially favorable for this technique. In the case of 51 Pegasi b (the first exoplanet found around a solar type star) and other exoplanets of this kind (also called **hot Jupiters**), the motion of the star was close to 50 m/s .

Exoplanet, Detection, and Characterization,

Fig. 3 The transit of HD209458b, as observed from the ground (After Charbonneau et al. 2000. (The figure is taken from Ollivier et al. 2009))

Thanks to the improving performances of high-resolution spectrographs, it is now possible to measure velocities smaller than 1 m/s, which allows a mass limit not far from a terrestrial mass. The extension of the velocimetry data base over two decades also allows searches for planets located at a few AU to a few tens of AU from their host star, that is, searches for planetary systems which might be more similar to the solar system.

The Method of Transits

Under favorable circumstances, the observer may be located close to the plane of a planetary system. In this case, the exoplanet periodically crosses the stellar disk. During this event, the flux of the star is reduced because of the presence of the occulting planet, and this flux variation can be measured if the stellar flux is continuously monitored with a very high stability. In the case of the solar system, the occultation of the Sun by Jupiter, as observed from a nearby star, would lead to a flux decrease of 1% (this is simply the square of the ratio between the planetary and solar radii). In the case of the Earth, the flux decrease would be only 0.01%.

The detection of hot Jupiters is very favorable to the transit method, as the occultation events repeat over a short timescale (a few days). Measuring flux variations of 0.01% is not achievable from the ground, but variations of the order of a

percent can be monitored from the ground. However, photometric data with exquisite accuracy can be obtained from space. The first observation of a planetary transit was achieved using a ground-based telescope by D. Charbonneau and his team in 2000 (Fig. 3). The hot Jupiter, HD209458b, was later observed with the Hubble Space Telescope (HST) with a much higher precision.

The great advantage of the transit method is that, combined with velocimetry, several planetary parameters can be derived: the radius (from the flux extinction), the mass (from the velocimetry), and thus the density. Physical characterization of the planet thus becomes possible, as will be discussed below.

Several ground-based monitoring programs have been developed for the systematic search for transits using small, robotic, wide-field telescopes. These programs are well designed for the search for giant exoplanets close to their stars. The Earth-like exoplanets, or even the rocky exoplanets, with a mass less than ten terrestrial masses, cannot be detected from the ground because the photometric stability is limited by the turbulence of the Earth's atmosphere and also by potential seismic activity. This is why space missions have been developed. Launched by the French space agency CNES in December 2006, the CoRoT space mission was the first

satellite designed for this project (and a complementary program of asteroseismology) which actually detected exoplanets. The instrument consisted of a 27-cm diameter telescope equipped with four CCDs (two for the exoplanet survey) which image a 7 square-degree field for a maximum period of 5 months. CoRoT had detected several tens of exoplanets of all kinds, and many more candidates which remained to be confirmed by velocimetry.

The next transit space mission was Kepler. This mission was launched in March 2009 and ended its primary operation in 2013. (The Kepler telescope has been used in the NASA K2 mission until 2018.) The instrument consisted of a 95-cm telescope equipped with 42 CCDs which observed a field of about 100 square degrees. Kepler was able to detect terrestrial size and smaller planets. Nearly 1,000 exoplanets have been detected, and over 4,000 unconfirmed candidates had been reported, among which some exoplanets with a mass close to the terrestrial one.

Following the Kepler mission, two new space telescopes, dedicated to the detection of transiting exoplanets, are currently in operation: TESS (Transit Exoplanet Survey Satellite), launched by NASA in 2018, and CHEOPS (Characterizing Exoplanets Satellite), launched by ESA and Switzerland in 2019. TESS is equipped with four 10-cm telescopes and can detect stars weaker than Kepler by a factor between 30 and 100, and its objective is to detect low-mass exoplanets. CHEOPS is using a 35-cm telescope and is searching for transits of already known exoplanets, in order to better characterize these systems.

The Microlensing Technique

The phenomenon of gravitational lensing is a peculiar aspect of Einstein's theory of relativity. As a consequence of the energy/matter equivalence, a photon is subject to gravitation just as classical baryonic matter. As a result, a photon approaching a stellar object is deflected relative to its direction of propagation. If a massive object is located on the line between the observer and the distant object being observed, the image of the latter is modified. In the case of a massive

deflecting object (usually a galaxy), the result is the well-known gravitational lensing effect observed on distant quasars.

When the mass of the deflecting object is low, the effect, called microlensing, is observed as a magnification of the signal of the source being observed. This magnification effect can be used to detect remote stars which were not observable before. The time of transit of the nearer object (the "lens") in front of the distant star lasts typically a few tens of days. Using this method, several groups have undertaken ground-based surveys to search for a population of brown dwarfs and thus to try to detect dark matter in the Galaxy.

This method is also of interest for exoplanets' detection, as the presence of a planet around the lensing star can be inferred from a special signature in the amplification curve of the distant (source) star. This method is very sensitive and has led to the detection of over 30 objects among distant stars. A peculiar object is the very small planet (OGLE-05-390L) of 5.5 terrestrial masses, located at 2.6 AU from its star (Fig. 4). The main disadvantage of the microlensing technique is that the method is neither predictable, nor repeatable. So, no physical characterization can be undertaken on these presumably planetary objects.

Comparison of the Different Indirect Methods

The advantages and limitations of the indirect detection methods can be summarized as follows:

- Astrometry is well adapted for the detection of massive exoplanets far from their stars. The method has been not so far usable from the ground, however much progress is expected from the ► [Gaia mission](#).
- Velocimetry has been the first tool for exoplanets' detection. Constant improvements in the instrumental performances have allowed the detection of exoplanets close in mass to terrestrial analogs. Mostly short-period exoplanets were detected in the first decade, but the time extension of the database has allowed the detection of more and more solar system giant-planet analogs with longer periods, as well a new class of planetary bodies with masses between 2 and 10 Earth-masses known as super-Earths.

Exoplanet, Detection, and Characterization,

Fig. 4 Light curve of a microlensing event for OGLE-2005-BLG-390Lb

- The transit method is well adapted to the detection of massive objects close to their star; ground-based observations are possible for giant exoplanets and are performed in the frame of several ground-based systematic campaigns. The limitation lies in the peculiar geometry of the planetary system which must be observed edge-on. The probability for such a geometry is about 10% for hot Jupiters. The transit method, when coupled with velocimetry, provides the confirmation of the planetary nature of the candidate detected by transit. The combination of both methods allows for characterization of the exoplanet with the determination of its period, mass, radius, and density. The detection of rocky planets by transit has been possible using space missions CoRoT and Kepler.
- The microlensing technique is very sensitive, and well adapted to low-mass objects distant from their stars. Exoplanets are found around distant stars, located in the halo of our Galaxy, and a statistical analysis of this population can be obtained from the ground by this method. However, there is no possible physical characterization of the detected objects, as the observations are not repeatable.
- Finally, the pulsar timing which led to the first detection of exoplanets is extremely sensitive to low-mass objects. However, the method is

limited to a small number of cases (pulsars with planets).

Direct Detection Methods

The direct detection of an exoplanet implies the detection of photons, at any wavelength, emitted by the exoplanet itself. The problem is thus to separate these photons from the stellar ones.

Spectrophotometric Measurements: Secondary Transits

We have mentioned above the transit observations as an indirect method of exoplanet detection. In addition, when the planet's flux is strong enough, the same observations can be used for a direct measurement of the exoplanet's flux during the secondary transit, when the planet passes behind the star. By measuring the total flux of the system, before, during, and after the secondary transit, it is possible to retrieve by difference the flux emitted by the planet's dayside, and even to measure its spectrum. The method has been successfully used in the infrared range on a few objects, mostly hot Jupiters. Spectroscopy has been achieved between 1 and 20 μm using ground-based observations, the HST and Spitzer (see below).

Imaging Techniques

Optimizing the spectral range of the observation results from a compromise between the

planet/star flux ratio (higher in the infrared) and the spatial resolution (higher in the visible range). Two spectral domains have been considered:

- In the near-infrared range, the star-planet pair can be resolved, using ► [adaptive optics](#) and coronagraphic techniques; the first image of an exoplanet, 2MASS1207b, was obtained using adaptive optics (see above).
- In the thermal infrared range, between 5 and 20 μm , the planet/star contrast is optimal; however, interferometry must be used to obtain the required angular resolution. A method has been proposed, called “nulling interferometry,” which allows the elimination of the stellar flux, by combining destructive interferences along the line of sight; if a planet is present at some distance from the line of sight, its signal can be detected if it corresponds to a bright fringe. These observations will have to be performed from space and still require important technological developments.

Significant developments have been achieved over the past 10 years in the near-infrared imaging technique. New instruments combining adaptive optics, coronagraphic masks, and sophisticated data processing algorithms have been mounted on very large telescopes (Keck, Gemini, VLT...). About 150 exoplanets have been detected by this technique (Fig. 5).

Radio Detection

The radio range, and in particular the decametric range, is especially favorable in terms of planet/star flux ratio. Indeed, planets like Jupiter which possess a strong magnetic field emit a nonthermal auroral emission, coming from the interaction between charged particles and the magnetic field in the polar regions. In the case of Jupiter, the intensity of this emission is comparable to that of the Sun. These emissions have special characteristics: in the case of Jupiter, they have durations shorter than 1 s, and their spectrum extends from about 20–40 MHz. There are, however, sources of noise at the same frequencies, coming both from the Galactic emission and from the Earth itself, including human activities. Still, radio-astronomers are studying the possibility of detecting radio emissions from exoplanets using large arrays of radio antennae like LOFAR in Europe, UTR-2 in Ukraine, and later SKA (the proposed Square Kilometer Array). Calculations predict that the radio emission of a Jupiter-like exoplanet at 0.2 pc could be detected with UTR-2; however, there is no nearby star closer than 1 pc. In the case of hot Jupiters, close to their stars, the radio signal would be accordingly enhanced and such objects could possibly be detected up to distances of 20–25 pc. This would open the possibility of actually detecting exoplanets with this technique. A search for radio emissions from three exoplanetary systems (55 Cancri, ν Andromedae, and τ Bootis) has been undertaken using the LOFAR low-beam

Exoplanet, Detection, and Characterization, Fig. 5 Detection of a newly formed exoplanet within the disk of a young star, PDS 70. The K7 star is 5 My old,

located at 113 pc. The exoplanet is located at 22 AU from the star, and its mass is about 7 jovian masses. (Source: Müller et al. 2018)

antenna. A tentative signal has been detected from τ Bootis, which remains to be confirmed (Turner et al. 2021).

An Inventory of Exoplanets, over 25 Years After the First Discovery

January 2023 marks 28 years after the discovery of 51 Peg b. About 5,200 exoplanets have been detected. Most of the objects have been found by transit photometry and velocimetry. About 16% of the objects belong to multiple systems.

Exoplanets are common in the Galaxy. Following Kepler statistics, it appears that the probability for a star to have an exoplanet is close to 1. This first estimate will have to be refined in light of more complete samplings, including the M dwarfs, by far the most numerous stars in the Galaxy. Also, there are still observational biases toward short-period and massive exoplanets, which are easier to detect.

The (Mass, Distance) Diagram of Exoplanets

Figure 6 shows a diagram of the exoplanets as a function of the distance to their host star

(in abscissa) and their mass (in ordinate). It can be seen that they can be assembled in three categories which correspond to the three major detection techniques.

There is a compact group of massive planets close to their host star. They are the hot Jupiters, which were first detected with the radial velocity method. Many of them are orbiting within 0.05 AU from their star (i.e., with a period of 4 days or less). These objects are so close to their star that, most likely, they are tidally locked with their star, in synchronous rotation, showing always the same hemisphere to it (as in the case of the Earth-Moon system). In view of the short distance between the star and the planet, strong temperature contrasts are expected between the day side and the night side of the planet. The second group includes smaller objects (super-Earths and Neptunes) close to their star. Most of them have been detected by the method of transits, at distances from their stars ranging between 0.03 and 0.3 AU. As in the case of hot Jupiters, they are expected to be in synchronous rotation. Finally, the third group includes massive objects at distances from their stars larger than a few UA. The most distant ones have been recently detected by

Exoplanet, Detection, and Characterization, Fig. 6 The mass-distance diagram of exoplanets. (Source: exoplanet.eu)

the direct imaging technique, and their number is rapidly increasing.

The absence of small objects distant from their stars is obviously an observational bias: they are the most difficult targets to identify, whatever detection method is used.

The Mass Distribution of Exoplanets and the “Brown Dwarf Desert”

The velocimetry method allows the detection of exoplanets, but also the detection of more massive stellar companions. If the object has a mass lower than 0.01 solar mass (or 13 Jupiter masses), its internal energy is not sufficient to generate the thermonuclear reactions leading to stellar nucleosynthesis; the object is called a planet. If its mass is between 0.01 and 0.08 solar masses (between about 13 and 80 Jupiter masses), the central temperature is sufficient for initiating the first cycle of thermonuclear reactions which destroys deuterium, but not the next cycle which would transform hydrogen into helium; the object is called a brown dwarf. Beyond a mass of 0.08 solar masses, the object is a star. Several stellar types are defined (O, B, A, F, G, K, M) as a decreasing function of their mass and temperature. The brightest and hottest stars have the shortest lifetime. The Sun, a G-type star, is a very ordinary star, in the middle of the range; its lifetime is about 10 Gy.

If we consider the distribution of stellar companions detected by velocimetry, we observe a bimodal distribution (Fig. 7), with a first peak between 0.001 and 0.01 solar masses (the exoplanets) and the other beyond 0.1 solar mass (the stars). The absence of objects between the two peaks is known as the “brown dwarf desert.” It probably illustrates the two different formation scenarios of these two classes of objects. Stars are formed from the collapse of a cloud fragment of interstellar matter; planets are formed by accretion of solid particles within the protoplanetary disk formed after the collapse of this cloud.

Inside the exoplanet population, the mass distribution also exhibits a bimodal distribution (Fig. 8). A first maximum appears around 0.03 Jovian masses (i.e., one terrestrial mass) and the

Exoplanet, Detection, and Characterization, Fig. 7 The bimodal mass distribution of stellar companions. The quantity $[M \sin i]$ is determined by velocimetry. The exoplanet population appears on the left side, and the stellar population is on the right side. The hole at the center is known as the brown dwarf desert. (The figure is taken from Ollivier et al. 2009)

second one is centered around one Jovian mass. This bimodal distribution could possibly be the result of the core accretion scenario, assumed to be valid for the Solar system; according to this scenario, planets are formed within the protoplanetary disk from the accretion of solid embryos (see below). However, it must be kept in mind that this curve may still be affected by observational biases.

A Wide Range of Eccentricities

Within the solar system, we are used to planets on almost concentric orbits, that is, with low eccentricities. Exoplanets are very different. With the exception of hot Jupiters whose orbits are very circular (possibly as an effect of strong tidal forces), exoplanets exhibit a large variety of eccentricities, in some cases as high as 0.90. A possible explanation could come from various types of interaction, especially between the planet and the protoplanetary disk. There is no clear apparent correlation between the masses of exoplanets and their eccentricities.

Exoplanet, Detection, and Characterization,

Fig. 8 The mass distribution of exoplanets.
(Source: exoplanet.eu)

A Large Number of Multiple Systems

Many multiple systems have been detected, and more are to be found. So far, the nearly 4,900 confirmed exoplanets have been found in about 3,600 planetary systems, including more than 800 multiple systems, with a number of planets ranging from 2 to 7. However, in view of the observational bias, multiple systems might be as common as single ones. Thus, in this view, the solar system is not an exception. Multiple systems are of special interest for dynamicists who can study their stability with numerical simulations.

The most famous of multiple planetary systems is the system of the star Trappist 1, discovered by the method of transit. This very small, 0.08 solar-mass M8 star is host to seven planets, all with a size comparable to the Earth. All orbits are coplanar. The whole system is very small, as all planets are located within 0.05 AU from their star. For comparison, in the Solar system, the closest planet, Mercury, is located at about 0.4 AU from the Sun.

The Effect of Metallicity

It is interesting to study the probability for a star to host a planet as a function of its relative fraction of heavy elements (i.e., elements heavier than helium), also called its metallicity. According to the scenario most commonly accepted for planetary formation, planets formed within a protoplanetary disk from the accretion of solid

particles. The higher the metallicity of the star, the more solid material should be available for planetary embryos; we should thus expect a positive correlation between the metallicity and the frequency of planets. This correlation is indeed observed in the case of giant exoplanets; it is not clear in the case of rocky exoplanets, and a larger sample will be needed before any firm conclusion can be reached. It should be also noted that the Sun, in spite of its low metallicity, hosts a system of eight planets, including four giant ones.

Scenarios for Planetary Formation

It is generally accepted that planets formed within a protoplanetary disk, resulting from the collapse of a rotating fragment of an interstellar cloud. These early phases of star formation have been observed on many young stellar objects, and this scenario is also believed to be responsible for the solar system formation. Within the disk, planets form from the accretion of solid particles. In the vicinity of the Sun, the temperature is such that only metallic compounds and silicates are in solid form. Because these elements are not very abundant in the Universe, the planets formed near the star are expected to be relatively small and dense: they are the rocky planets. In contrast, at farther distances from the star, where the temperature drops below about 200 K, most of the simple

molecules (H_2O , NH_3 , CO_2 , CH_4 , H_2S , ...) are in the form of ices. These compounds can thus be incorporated in planetary nuclei which can reach a mass of 10–15 terrestrial masses. Calculations show that beyond this limit, the gravity field of the nuclei is sufficient to capture by gravitational collapse, the surrounding material, which is mostly composed of hydrogen and helium. The process leads to the formation of giant planets, with a large volume (mainly of gas) and a low density. The collapse of the nebula surrounding such a planet leads to the formation of a small disk, which explains the presence of satellites and ring systems in the equatorial plane of the giant planets. In the case of the solar system, this nucleation formation scenario is fully consistent with the presence of terrestrial planets within 2 AU from the Sun and giant planets beyond 5 AU.

How can we then explain the presence of giant exoplanets in the immediate vicinity of their star? The most common explanation proposed by theoreticians is planet migration. As an effect of interactions between the planet and the protoplanetary disk (mostly the gaseous disk), a planet can migrate from the outside to the inside and come in the vicinity of the star. A question is still open: what is the mechanism which stops the migration at 0.05 AU from the star? According to some dynamical models, after a period of high [▶ eccentricity](#), the planet could come into an approximately circular orbit; the strong gravity field of the star would tidally lock the planet to it.

Another question is to be raised: why was there no major migration in the solar system? According to dynamical simulations, a moderate migration of giant planets has also occurred in the solar system (Tsiganis et al. [2005](#)). According to these models, the small mass of Mars could be the result of the inward migration of Jupiter from 3.5 to 1.5 AU and its subsequent outward migration due to the pull of Saturn to orbits beyond 3.5 AU.

From Detection to Characterization

After 25 years of intense observing campaign, we have discovered a wide variety of exoplanets, with different masses and orbital properties. We

are now entering a new research era, the one of exoplanet characterization. The aim is to understand the nature of their atmospheres, and the main tool for it is infrared spectroscopy of transiting exoplanets.

What Kind of Exoplanets Can We Expect?

We can have a first guess of the possible nature of an exoplanet's atmosphere, knowing its mass and its distance to the star, just by analogy with solar system planets and satellites. The most important parameter is the stellar distance, as compared with the line of ices of the system (the "[▶ snow line](#)"). This limit corresponds to water condensation and occurs at a temperature of about 180 K. Within this limit, we expect rocky exoplanets; beyond it, we expect either icy planets, if their mass is below ten terrestrial masses, or giant planets (i.e., with some fraction of protostellar gas) if they are bigger. In the first case, we would expect a (CO_2 , N_2) atmosphere, with some amount of H_2O and CO ; in the latter case, we would expect a reduced atmosphere, dominated by hydrogen and helium, with a minor contribution of CH_4 , NH_3 , and other hydrogenated molecules. Of course this "first guess" classification is extremely simplified, as many parameters (albedo, rotation period, obliquity, possible greenhouse effect, magnetic field, etc.) might be involved. Even more importantly, no migration is assumed in the above scenario, and we know that it is a common process encountered in planetary systems.

The Infrared Spectrum of an Exoplanet

As in the case of any solar system object, the infrared spectrum of an exoplanet shows two main components, the reflected stellar radiation which peaks in the visible range for a solar-type star, and a thermal component with peaks in the infrared range corresponding, to first order, to the blackbody radiation at its effective temperature. The balance between the two components depends upon the albedo (reflectivity) of the exoplanet. For solar system objects, the albedo ranges typically between 0.05 (comets) and 0.3–0.6 (planets and icy satellites). In the solar reflected regime, atmospheric signatures are observed in absorption in front of the stellar flux. In the

thermal regime, the situation is more complex, as the molecular features may appear in absorption or emission, depending upon the thermal vertical gradient in the atmosphere. For solar system planets, the signatures are in absorption if they are formed in the troposphere (where the temperature decreases with increasing altitudes), and in emission in the stratosphere (where the temperature increases with altitude). Understanding the thermal emission of an exoplanet thus simultaneously requires the determination of its thermal vertical structure.

Infrared Spectroscopy of Transit Exoplanets

There are two ways of measuring the spectrum of a transiting exoplanet. During the primary transit, when the planet passes in front of the stellar disk, its atmospheric constituents can be observed in absorption in front of the stellar flux. Before and after the secondary transit, when it passes behind the star, the planet can be observed in emission. In both cases, the planetary flux is retrieved by difference with the stellar flux without the planet.

Over the past 20 years, spectroscopic observations of a few hot Jupiters (HD209458b, TrES-1, HD439733b) have been obtained in both modes. Using primary transits, transmission spectra have been obtained in the visible and near-infrared

ranges, using the Hubble Space Telescope and ground-based observations. Atomic lines of H, O, C, Na have been observed, as well as emission bands of CH₄ and H₂O. Secondary transits have been used to measure the exoplanets' emission spectra with the Spitzer satellite in the near- and mid-infrared range. Using both primary and secondary transits, many signatures have been identified, including those of CH₄, H₂O, CO₂, CO, NH₃, HCN, C₂H₂, and some radicals (Fig. 9). This field of research is rapidly exploding and more discoveries are expected in the coming decade.

In addition to transit spectroscopy, the imaging technique is more and more associated with spectroscopic capabilities. This is the case of the SPHERE instrument on the VLT, which is equipped with a low-resolution spectrometer in the near infrared, thus allowing the characterization of young and warm planets located at several AU from their host star.

Future Directions

The number of known exoplanets – about 5,200 – now allows statistical studies to be performed, and the characterization of their atmospheres is becoming technically feasible. In the future,

Exoplanet, Detection, and Characterization,

Fig. 9 Detection of H₂O and CH₄ in the atmosphere of a hot Jupiter, HD189733 b, using the near-infrared spectrometer of the Hubble Space Observatory. The black triangles are the data. The curves show atmospheric models including H₂O (in blue) and (H₂O + CH₄) in orange. Both molecules are clearly detected. (Source: Swain et al. 2008)

studies will use both indirect and direct detection techniques.

The radial velocity method will take advantage of the advent of extremely large telescopes, expected to get their first light within the coming decade. In parallel, the extension of the spectral range to the near infrared range will give access to K and M stars, more numerous than the Sun. Large telescopes will also be precious for the development of imaging techniques, as well as the transit spectroscopy of large exoplanets around bright stars in the infrared spectral windows accessible from the ground.

In space, the astrometric Gaia mission, in operation since 2013, is expected to bring revolutionary results by making possible, within a few years, the detection of thousands of exoplanets by astrometry. In December 2021, the launch of the James Webb Space Telescope, with its two spectrometers, in the near infrared (NIRSpec) and the mid-infrared range (MIRI), has been a major step forward for the spectroscopy of transiting exoplanets. However, in view of the long exposure times and the strong competition for observing time, the number of potential targets will be limited. Other space missions devoted to exoplanet detection and characterization have been scheduled for the coming decade and beyond. Following TESS and CHEOPS, presently in operation, the European PLATO mission, with enhanced capabilities, is expected to be launched around 2026. Two years later, the Ariel mission, also developed by ESA, is expected to bring a complete inventory of the spectral characteristics of about 1000 exoplanets.

[Extrasolar planets](#)

Definition

Exoplanets, also known as extrasolar planets, are planets beyond the solar system, orbiting around stars other than the Sun. The discovery of the first exoplanet happened in 1992 when three planets were discovered around the pulsar PSR 1257+12 (Wolszczan and Frail 1992). The first planet around a Sunlike star (hence the name *extrasolar* planet) was discovered in 1995 by Mayor and Queloz.

Overview

The quest for planets beyond the solar system has achieved spectacular progress during the last 25 years. In the few years to come, astronomers

will discover tens of thousands of planets (thanks to Gaia for instance). Many of which will be similar to Earth, orbiting Sun like stars, and some of which could possibly support life as we know it.

After the discovery of the planetary system around pulsar PSR 1257+12 in 1992, the initial discoveries of extrasolar planets involved giant planets with enough mass to induce measurable reflex motions in the stars they orbited, thus implying the presence of unseen planets. Unlike what many had anticipated that planets would be detected by astrometry through identifying stellar motion in the plane of the sky and across the line of sight, it was the stellar motions along the line of sight (i.e., perpendicular to the plane of the sky) based on measurements of the changes in radial velocities using Doppler spectroscopy at optical wavelengths that opened the exoplanet floodgates. The conventional thinking was dominated by the architecture of the solar system, with the giant planets in wide circular orbits out past the ► [snow line](#), where conditions were cold enough for them to form. The first radial-velocity orbit for an unseen companion that could be called a giant planet (if the orbit happened to be oriented nearly edge on) was published in 1989, but it defied conventional wisdom on three counts. The orbital period of only 84 days placed it far inside the snow line, where conditions would have been too hot for a gas giant to form; the orbit was eccentric, unlike any of the giant planets in the solar system, and the mass was at least ten times that of Jupiter, which was uncomfortably large (and close to the mass of a small ► [brown dwarf](#)). Thus, most astronomers dismissed the unseen companion of HD114762 (Latham et al. 1989) as a star or brown dwarf in an orbit seen nearly face on (thus minimizing the observed Doppler effect, which only measures the velocity along the line of sight). It was assumed that the observed orbital amplitude of 0.5 m/s was small because of projection effects and not because the mass of the companion was small enough to be a planet.

In 1992, the detection of a system of unseen planets orbiting the pulsar PSR B1257+12 was

announced (Wolszczan and Frail 1992). Unlike the case of HD114762, these planets were detected based on periodic variations in the arrival times of the radio pulses from their rotating neutron host star. Follow-up observations, using the detection of perturbations in the pulse arrival times consistent with gravitational interactions involving planetary-mass objects, soon demonstrated that the masses were indeed small and similar to the mass of Earth. Astronomers were puzzled how planets could survive the ► [supernova](#) event that created the neutron star or alternatively how they might have formed from the leftover debris, but it seemed clear that if planets could find a way to live around a pulsar, maybe they would prove to be common around normal stars similar to the Sun.

That is how the search for planets around Sun like stars stood. Because our solar system was used as a template, the search for giant planets (which could induce larger reflex motion on their host stars) was focused on distances beyond the snow line. It was in 1995 when an orbit for 51 Pegasi was announced that implied an unseen companion with a mass similar to Jupiter and a remarkably short period of only 4.2 days (Mayor and Queloz 1995). Soon after this announcement, many argued that because of the uncertainty in the inclination of the planet's orbit and therefore the value of its actual mass, the unseen object may in fact be a more massive body such as a brown dwarf. The initial resistance was, however, overwhelmed by the announcement of several other low-Doppler-amplitude orbits implying giant planets, often in eccentric orbits close to their parent stars, some of them quite massive. Too many were being found for them all to lie in orbits facing the Earth and thus to possibly be brown dwarfs. A population of extrasolar planets was being revealed, although for any particular candidate the mass could not be pinpointed until the inclination of the orbit to the line of sight could be established.

Ambitious Doppler surveys of hundreds and even thousands of solar-type stars rapidly expanded the known population of radial-velocity planet candidates. As the surveys were sustained

over longer durations, planets with longer periods were discovered. As the instrumental techniques improved and the velocity precisions improved, the discoveries were extended to smaller masses as well. As richer data sets were accumulated, systems with more than one planet were discovered. Finally, in the search for habitable planets, the surveys were focused on cool, low-mass stars. By now, a new class of bodies known as *super-Earths* has been identified, some of which with masses only a few times that of Earth, orbiting in the habitable zones of their host stars. These accomplishments are described in more detail in the entry ► [“Radial-Velocity Planets”](#).

To remove the ambiguity in the actual mass of an unseen companion revealed by a radial-velocity orbit (traditionally termed as a ► [spectroscopic orbit](#) by astronomers), the inclination of the orbit to the line of sight must be established so that the observed orbital velocity can be corrected for projection effects. Astrometry of the orbital motion on the plane of the sky can in principle resolve this ambiguity because of the extra information provided by the motion in two dimensions across the line of sight. Indeed, in a few cases, astrometry has provided orbital inclinations for radial-velocity planets. However, the real breakthrough for deriving actual masses for planets (and therefore confirming their planetary nature) came with the discovery of systems with orbits oriented close enough to be edge on as seen from the Earth so that the planets transited across the face of their host stars. The first of such transiting planets was HD209458 (Charbonneau et al. 2000; Henry et al. 2000). Detection of planets using transit photometry opened a new chapter in the exoplanetary science. Not only does this technique allow the actual mass of the transiting planet to be determined (the orbital inclination with respect to the plane of the sky is now known and is near 90°), it also enables one to determine the radius of the planet. The amount of stellar light blocked by the shadow of the planet allows the area, and therefore planet's radius, to be measured. Knowing the mass and radius of a planet, its bulk properties such as the density and surface gravity can be calculated.

It turns out that transiting planets also provide a rich variety of opportunities to learn additional planetary astrophysics. This includes observations of planetary atmospheres during both the transits and the secondary eclipses (sometimes called occultations), when the planet disappears behind its star, yielding the temperature and chemical composition of the planet's atmosphere. In some cases, the thermal emission from the planet has been tracked as it moves around in its orbit, thus revealing the changes in temperature as more of the dayside comes into view and providing insights into the weather on the planet. The degree of the alignment of the planet's orbit with the equator of its host star can also be determined in transiting system. Using the ► [Rossiter-McLaughlin effect](#), one can determine the tilt of the stellar spin axis to the planetary orbit which can provide important clues about the history of the formation and evolution of the planet. Similar to planetary systems detected by radial velocity, additional planets may exist in transiting systems (which may or may not transit). These planets may reveal their presence by perturbing the times at which transits of other planets are observed. Known as *transit-timing variation (TTV)* method, these variations have been used to detect several planets by the *Kepler* space telescope. Perhaps surprisingly, the detailed shape of a transit can pin down the density of the host star, and if the shape is determined with sufficient precision, details such as the oblateness of the planet due to rotation can also be determined. These topics are treated in more detail in the entry ► [“Transiting Planets”](#).

An entirely different approach to the detection of unseen planets orbiting distant stars takes advantage of an effect called gravitational microlensing. When the line of sight to a distant star (the source) is intersected very precisely by an intervening star (the lens), the light of the distant star is magnified by the lensing effect of the gravity of the intervening star. As the relative motion of the two stars changes the exact alignment, the changing magnification produces a light curve that first brightens and then dims in a way that can reveal information about the

lensing star (e.g., its mass). If a planet is orbiting the lens in such a way that it passes close to the line of sight, it can affect the brightening and introduce a feature in the light curve. Although the precise alignment needed to produce a microlensing event is very rare, and the alignment to reveal an orbiting planet is even more rare, surveys to monitor hundreds of millions of stars have detected and characterized several microlensing planets. These results and some details of the technique are described in the entry [“Microlensing Planets”](#).

An attractive way to study the characteristics of an extrasolar planet would be to isolate its light from that of the host star to produce a direct image for further studies such as astrometry to reveal the planet's orbit or spectroscopy to explore the structure and chemical composition of its atmosphere. Such experiments present daunting technical challenges because of the extreme brightness ratio and the tiny angular separation between the planet and its host star, even for the nearest systems. Direct images of a few giant planet candidates in wide orbits around hot stars have now been obtained both with special techniques from the ground and with the *Hubble Space Telescope*. Earth-sized planets will be much more difficult to image and will require specialized space missions or ground-based “extremely large telescopes.” More details can be found in the entry ► [“Direct-Imaging, Planets”](#).

Exopolymers

Lucas J. Stal
Department of Marine Microbiology, Royal
Netherlands Institute of Sea Research (NIOZ),
Yerseke, The Netherlands

Keywords

Biofilm · Cyanobacteria · Diatoms ·
Microalgae · Polymers

Synonyms

EPS; Extracellular polymeric substances; Extracellular polymers; Extracellular polysaccharides

Definition

Exopolymers are polymers that are deposited outside the (microbial) cell. These polymers are predominantly composed of carbohydrates, but many contain various other components such as proteins, DNA, and glycolipids. Some exopolymers consist of neutral sugars such as glucose, while others are acidic in nature and contain a variety of charged groups such as the uronic acids, carboxy groups, sulfated sugars, or pyruvate groups. The molecular structure and composition of exopolymers is therefore highly diverse and complex. Exopolymers form the matrix of biofilms in which the microorganisms are embedded but also serve a plethora of other functions.

Overview

Exopolymers are by definition polymers that are deposited outside the cell wall. These include sheaths or investments in which the cell, but often also aggregates or chains or threads of cells, are wrapped and represent a more or less structural part of the organism. Such sheaths may be highly structured and may have a typical morphology, while other infestations are more diffuse. Other exopolymers do not have a close association with the cells that produce them. They are exuded into the environment and “dissolve” as colloidal exopolymers in the water or form in the benthic environment the biofilm matrix in which the microorganisms are embedded.

Exopolymers that are exuded into the environment are usually the result of unbalanced growth, for instance, when photosynthetic organisms fix CO₂ but are limited by nutrients. In that case, the fixed carbon cannot be accommodated by the synthesis of structural cell material and will be deposited as polysaccharide. Part of it will be stored intracellularly as a reserve compound but the bulk will find its way as colloidal exopolymers. The same may be the case with chemotrophic microorganisms that live at the expense of energy-rich but nutrient-poor resources.

Exopolymers can also exude as a result of the gliding motility by some bacteria, notably by ► [cyanobacteria](#). The exopolymers are exuded through specific pores in the cell wall and interact with the substrate on which the organism glides, leaving behind a trail of exopolymer. The mechanism of gliding motility is still poorly understood.

Exopolymers are not just waste products. They may serve a variety of important functions for the organism that produces them as well as for the ecosystem as a whole. It has been shown that benthic diatoms metabolize the exuded exopolymers as a carbon and energy source in the dark. Exopolymers form the matrix of biofilms. They may be important for attachment of microorganisms to surfaces. This may be important for the success of the organism but represents also a problem known as fouling. Exopolymers form coherent networks and matrixes that may interact

covalently with mineral particles, resulting in sediments with a high erosion threshold. Hence, exopolymers have found application in sediment stabilization. Exopolymers may bind calcium and magnesium ions, thereby controlling calcification. It may act as an anti-calcification agent, but it may also allow local calcium carbonate precipitation and hence the tertiary structure of the polymer may determine the morphology of the calcium carbonate. This is the case with the calcium carbonate platelets known as coccoliths, which are produced by certain marine microalgae. Exopolymers protect the microorganisms from being grazed and immobilize (heavy) metals and other toxic compounds and antibiotics. The latter is an important problem for curing infections by pathogenic bacteria, while the former has found application in bioremediation of polluted soils. Many exopolymers may form a gel through the absorption of large amounts of water. This gel protects the organism from desiccation. Exopolymers can also scavenge important nutrients from the environment, thereby providing the biofilm organisms with an important advantage compared to free-living pelagic microorganisms. Finally, exopolymers can act as flocculants. Some benthic cyanobacteria have been shown to produce it in order to bind mineral particles, thereby clearing in the water column above them.

Exothermic

Jacques Reisse

Université Libre de Bruxelles, Brussels, Belgium

Definition

The term exothermic refers to a reaction or a physical transformation which releases energy if it takes place at constant volume or which releases ► [enthalpy](#) if it takes place at constant pressure. A familiar exothermic reaction is the ► [combustion](#) of coal. The enthalpy change (ΔH) during an exothermic reaction or transformation taking place at constant pressure is negative by definition. The enthalpy release takes the form of a heat release.

Dust particles · Exoplanet · Interplanetary
dust · Scattering

Synonyms

Exozodi

Definition

The exozodiacal light is the analog in extrasolar planetary systems of the ► [zodiacal light](#) seen in the solar system. It corresponds to the light emitted by the central star, scattered – or reemitted in the infrared – by interplanetary small dust particles concentrated in the mean orbital planetary plane, that is, the local ► [ecliptic](#). It is often abbreviated as *exo-zodi*. This may be a strong emission that can prevent direct detection of planets belonging to the system.

Overview

In the solar system, the zodiacal light appears as a flame-shaped glow just above the horizon, visible

to the naked eye in good atmospheric conditions and when the moon has not risen. It is seen only toward the west after sunset or in the east before sunrise and is aligned along the zodiacal belt, hence its name. It is due to sunlight reflected by dust particles of 1–100 μm in size, concentrated in the plane of the ► [ecliptic](#), mainly in its central region (approximately up to the asteroid belt). Because the dust particles are heated by the sunlight to a temperature comparable to the Earth's (300 K), they also emit in the infrared. It is generally admitted that extrasolar planetary systems must harbor a similar content of dust and thus exhibit an analog of the zodiacal light in the visible and infrared. The origin of this dust can be primitive material in the ► [protoplanetary disk](#), but more often in mature systems, it corresponds to debris left after planet formation when the remaining ► [planetesimals](#) suffered collisions and evaporation. The question of the intensity of the exozodiacal light is extremely important when dealing with the direct detection and characterization of planets in the ► [habitable zone](#), because exozodiacal light intensity may be so large that it would dominate by several orders of magnitude the signal from a planet. In the solar system, for instance, the zodiacal light is 300 times stronger than the emission of the Earth at a wavelength of 10 μm . The name exozodi was proposed as an abbreviation when its importance was realized and discussed in its details. It is generally assumed that the detection of an earthlike planet should be possible, provided that the exozodi does not exceed ten times the solar system value. A consequence is that before launching an

Exozodiacal Light,

Fig. 1 HST coronagraphic image of the star Fomalhaut at 0.6 μm , showing together the dust belt responsible for the exozodiacal light emission and the planet Fomalhaut b (*white square*) just within the inner boundary of the dust belt, at two different dates

expensive space mission that aims at direct detection of exoplanets, precursor missions or possibly measurements from the ground should assess the relative frequency of large and medium exozodi intensities in the visible and in the infrared. Figure 1 shows an image of the exosystem Fomalhaut where the exozodi is resolved as a ring and contributes to the background against which a planet has been directly detected (Kalas et al. 2008). A few stars have been identified as exhibiting an exozodiacal light, at least in the infrared domain: Beta Pictoris and 51 Ophiuchus are two examples.

[EXPOSE-E](#); [EXPOSE-R](#); [EXPOSE-R2](#)

Definition

EXPOSE-E, EXPOSE-R, and EXPOSE-R2 are exposure facilities developed by ESA in the 2000s and 2010s to investigate the effect of the space environment (especially energetic radiations) on various chemical and biological samples. EXPOSE-E was installed on the ► [International Space Station](#) outside of the European Columbus module on the European Technology Exposure Facility (EuTEF) from February 2008 to August 2009, while EXPOSE-R was installed outside the Russian module Zvezda from March 2009 to March 2011. EXPOSE-R2 was a reload of EXPOSE-R with new experiments, which was exposed (also outside Zvezda) from October 2014 to February 2016.

Overview

A picture of one of the EXPOSE facilities is shown in Fig. 1. Data from six temperature sensors connected to the three trays, four UV-B sensors, and one radiometer were recorded.

Experiments selected by ESA to be implemented on EXPOSE-E, EXPOSE-R, and

EXPOSE, Fig. 1 The EXPOSE-R2 facility (480 × 520 × 327.5 mm) outside the International Space Station. EXPOSE facilities are made of three experiment trays into which four square sample carriers

(77 × 77 × 26 mm) are fitted (Credit Roscosmos). In most of the experiments, one layer of samples is exposed to space, while another layer is fitted just below the first one to be used as flight controls

EXPOSE, Table 1 Astrobiology experiments selected after the first call of ESA in 1996 and finally accommodated on EXPOSE-R

Experiment	Topic of research	Principal investigator

EXPOSE-R2 are presented in Tables 1, 2, and 3 (Rabbow et al. 2009; Cottin et al. 2017).

EXPOSE experiments series have provided a large amount of data about the photostability of organic compounds in the context of the study of extraterrestrial environments such as comets, (micro)meteorites, the surface of Mars, the atmosphere of Titan, or interstellar medium (see, e.g.,

Stalport et al. (2019) or Baratta et al. (2019)). Furthermore, results are helping to build strategies of detections of the targeted samples or their photoproducts with telescopes, space probes, or rovers. Regarding biology, it has allowed exploring the limits of life in extreme environments and how bacteria can cope with high doses of radiation for a long duration. Enlightened hypotheses about

PSS	Study of the stability of organic compounds with a prebiotic relevance under space and Mars-like conditions	H. Cottin, LISA/UPEC – Créteil (France)

how microorganisms could survive in the Martian environments, or in meteorites ejected from one planet to another, can be derived from EXPOSE results (see, e.g., Billi et al. (2019), de Vera et al. (2019)).

One of the main limitations of EXPOSE was that scientists only had information about the samples before shipping them to space and then after their return in laboratories. This is one of the reasons why EXPOSE experiments series were discontinued by ESA after EXPOSE-R2 to be replaced by a new generation of exposure facilities allowing to monitor the samples during the exposure.

Exposed Surface Bioburden

Catharine A. Conley
NASA Headquarters, Washington, DC, USA

Definition

The term “exposed surface ► [bioburden](#)” is used to indicate the number of viable ► [microorganisms](#) that are carried on internal and external spacecraft surfaces that are available for particulate and gas exchange, and from which microorganisms could reach a planetary environment following the nominal landing of a spacecraft.

Synonyms

[Exposure platforms](#); [Exposure trays](#)

Definition

Exposure facilities are technical devices attached to the outer shell of a spacecraft with the purpose to expose ► [organic molecules](#), ► [microorganisms](#), and other small biological systems to outer space or to selected parameters of this extreme environment.

History

Soon after the advent of space flight, the accessibility of space has been used to study specific questions of astrobiology, such as the role of stellar ► [UV radiation](#) in the evolution of potential precursors of life, the role of the UV radiation climate in prebiotic and biological evolution on Earth or any other celestial body, and the likelihood of viable interplanetary transfer of life and the limiting factors of ► [Panspermia](#). First attempts were already performed during the Gemini program (Hotchin et al. 1968); they were continued in a more sophisticated manner during the Apollo program and up to the present studies on the ► [International Space Station \(ISS\)](#) (Horneck et al. 2010).

Overview

To expose chemical or biological samples to outer space or selected parameters of this extreme environment, several exposure facilities were developed for attachment to the outer shell of spacecraft (Table 1).

The first sophisticated exposure device was built in 1972 by ► [NASA](#), the Microbial Ecology Evaluation Device (► [MEED](#)) for the Apollo 16 mission (Taylor et al. 1974). MEED was mounted to the distal end of the TV boom of the Command Module during the extravehicular activity phase of the trans-Earth coast. It was composed of 798 sample cuvettes with quartz windows as optical filters with the optional provision of ventilation holes for access to space vacuum (Fig. 1). Using a solar positioning device, MEED was oriented directly perpendicular to the sun. In 1983, Spacelab 1 (SL 1) carried the exposure facility ES029 in its cargo bay (Horneck et al. 1984). ES029 consisted of an exposure tray partitioned in four square quartz-covered compartments (Fig. 2). Two of the compartments were vented to the outside, allowing access to space vacuum. The other two compartments were hermetically sealed with a constant pressure of 10^5 Pa. Each compartment accommodated 79 dry samples in the upper layer, allowing UV

exposure, and the same number was kept in the bottom layer as flight dark controls. UV-irradiated samples were placed beneath an optical filtering system composed of interference filters for narrow wavebands (220 nm, 240 nm, 260 nm, and 280 nm) and neutral density filters. A non-transparent shutter with optical windows was used to achieve precise irradiation intervals during the “hot phase” of the mission, when during several orbits the cargo bay of the shuttle was perpendicularly pointing towards the sun. The samples were exposed to space vacuum for 10 days and for predefined periods (from 19 min to 5 h 17.5 min) to solar UV radiation. The temperature ranged from 17 °C to 35 °C, the highest values occurring during the “hot phase” of the mission. A similar device was flown in 1993 with the experiment UVRAD during the German SL D2 mission that provided a “hot phase” during two orbits at the end of the mission.

Long-term exposures of organic chemical compounds and microorganisms to space started with the NASA ► [Long Duration Exposure Facility \(LDEF\)](#) and were continued with the European Retrievable Carrier (EURECA) mission (Fig. 3) (Innocenti and Mesland 1995), and the French PERSEUS mission on the Russian MIR station (Rettberg et al. 2002). The longest exposure of microorganisms to space, about 6 years (1984–1990), was achieved during the LDEF mission within the German experiment Exostack (Horneck et al. 1994). Frequent opportunities for short-duration exposure experiments (up to 15 days) of molecules and biological systems were provided by ESA’s Biopan facilities, cylindrical pan-shaped containers with a deployable lid mounted on the outer surface of the descent module of a Russian Foton satellite (Fig. 4) (Demets et al. 2005). The Foton satellite was also used to study the mineral decomposition and microbial survival during atmospheric reentry within the ► [STONE](#) experiments (Brandstätter et al. 2008; Cockell et al. 2007; de la Torre et al. 2010).

Advanced exposure facilities with up to four times the capacity of the ES029 experiment of SL 1 were developed by the ► [European Space Agency \(ESA\)](#) with the Exobiology Radiation Assembly (ERA) for the ► [EURECA](#) mission

Exposure Facilities, Table 1 Exposure facilities used on space missions to study the stability of organic molecules and the survival of biological systems in outer space (Horneck et al. 2010)

Year	Mission name	Mission characteristics	Exposure facility	Exposure duration	Space parameter studied
1966	Gemini IX and XII	Earth orbit (300 km alt)	Collecting/exposure device	16 h 47 min (GIX) 6 h 24 min (GXII)	Space, solar UV
1972	Apollo 16	Lunar mission	MEED	Vacuum: 1 h 20 min, UV: 10 min	Space vacuum; solar UV: 254, 280 nm
1983	Spacelab 1	Earth orbit (240 km alt.)	ES029	Vacuum: 9 days, UV: 19 min–5 h 17.5 min	Space vacuum; solar UV: >170; 220; 240; 260; 280
1984–1990	LDEF	Earth orbit (500 km alt.)	Exostack	2107 days	Space vacuum; solar UV
1992–1993	EURECA	Earth orbit, sun pointing	ERA	327 days	Space vacuum; solar UV: >110; >170; >280; >295; 220; 230; 260; 290 nm
1993	Spacelab D2	Earth orbit	RD-UVRAD	Vacuum: 10 days; UV: 5–120 min	Space vacuum; solar UV: 190; 210; 220; 230; 260; 280; >190; >304; >313; >314; >315; >316; >317 nm
1994	Foton 9	Earth orbit	Biopan-1	14.8 days	Space vacuum; solar UV
1997	Foton 11	Earth orbit	Biopan-2	10 days	Space vacuum. solar UV
1999	Foton 12	Earth orbit	Biopan-3	12.7 days	Space vacuum. solar UV
1999	MIR-Perseus	Earth orbit	Exobiologie	98 days	Space vacuum, solar UV
1999	Terrier Black Brant Rocket	Ballistic flight <304 km alt.	SERTIS	395 s	Space vacuum, solar EUV (30.4 nm)
2004	Terrier Mark 70-Improved Rocket	Ballistic flight <304 km alt.		350 s	High speed atmospheric entry
2005	Foton-M2	Earth orbit	Biopan-5	14.6 days	Space vacuum; solar UV: >170; >280; >320; >400 nm
			Stone-5		Meteorite entry in Earth's atmosphere
2007	Foton-M3	Earth orbit	Biopan-6	10 days	Space vacuum, solar UV: >110; >200; >290; >400 nm
			Stone-6		Meteorite entry in Earth's atmosphere
2008–2009	ISS-EuTeF	Earth orbit	EXPOSE-E	1.5 years	Space vacuum; solar UV: >110 nm; simulated Martian atmosphere and UV climate: >200 nm
2009–2011	ISS	Earth orbit	EXPOSE-R	~2 year	Space vacuum, solar UV: >110; >200 nm

(Fig. 3) and the ► **EXPOSE** facilities attached to the ISS (Rabbow et al. 2009). One EXPOSE unit consists of three trays (Fig. 5), each housing four compartments similar to those of the SL exposure

trays and of ERA. The EXPOSE-E facility was mounted during extravehicular activity to the European Columbus Module of the ISS as part of the European Technology Facility (EuTeF)

platform in February 2008 and retrieved in September 2009. Experiments on prebiotic chemical evolution were located in one tray of EXPOSE-E; the other two trays accommodated different microbial systems, either exposed to outer space conditions (space vacuum and solar UV spectrum of $\lambda > 110$ nm) or to simulated Mars surface climate (600 Pa pressure, 95% CO₂, and solar UV of $\lambda > 200$ nm). The second EXPOSE facility, EXPOSE-R, was launched in November 2008 and will remain attached to the URM-D platform, an external ISS facility at the Russian Zvezda module, for about 2 years. EXPOSE-E

and EXPOSE-R house a total of 13 different experiments that are performed in international cooperation (Baglioni et al. 2007). Before launching into space, all EXPOSE experiments were tested in carefully designed ground simulation experiments and in an experiment sequence test using the Planetary and Space Simulation Facilities (PSI) at the ► [German Aerospace Center DLR](#). The EXPOSE experiments will be continued with EXPOSE-R2.

Extinct Radionuclides

Daniele L. Pinti
GEOTOP Research Center for the dynamics of
the Earth system, Université du Québec à
Montréal, QC, Canada

Synonym

[Short-lived radionuclides](#)

Definition

Extinct radionuclides are atoms with unstable nuclei that have undergone radioactive decay into atoms of another element in a geologically short time; usually, half-lives of parent nuclides range from 80.8 Myrs (Plutonium-244 decay to xenon isotopes) down to 60,000 years (Lanthanum-137 decay to Barium-137). These elements, which originated from processes of stellar nucleogenesis in supernovas, are now extinct in nature because of their short half-lives, relative to the age of the Earth (4.5 Ga). A parent nuclide is considered as extinct after seven half-lives. An example is ^{26}Al , with a half-life of 0.7 Ma, which decays into ^{26}Mg . After 3.5 Myrs, the ^{26}Al could be considered as extinct. These radionuclides allow dating of objects formed early in the history of the solar system. Indeed, these objects contain traces of the daughter elements produced by decay of the incorporated parent nuclides, prior to their extinction. Intense decay heat generated by these radionuclides is thought to have allowed the total melting of medium- to small-size planetary bodies, driving early planetary differentiation.

Extinction, Interstellar or Atmospheric

Daniel Rouan
LESIA, Observatoire Paris-Site de Meudon,
Meudon, France

Definition

The extinction is the decrease of the light intensity of a celestial object due to scattering and/or absorption by an intervening medium. The medium can be of telluric origin (molecules, aerosol in the atmosphere) or astrophysical (small dust particles in the ► [interstellar medium](#)); in the later case one speaks of interstellar extinction. Extinction is measured in ► [magnitudes](#) and the wavelength at which it applies should be indicated. The interstellar extinction is larger in the blue than in the red and becomes less and less important as the wavelength increases in the infrared domain. Because of this differential effect, extinction is responsible for the so-called *reddening* of distant stars. Reddening is characterized by the ► [color excess](#). The radio domain is essentially not affected by extinction. Interstellar extinction is generally noted A_F , where F is the symbol of the wavelength considered (U, B, V, etc.), defined by a passband filter. When no indication is given, it is assumed that the extinction is in the visible band (V). Typical extinction by the average ► [interstellar medium](#) in the plane of our Galaxy is $A_V = 2 \text{ mag/kpc}$ (1 kpc is about 3000 light-years).

Extraterrestrial Delivery of Organic Compounds

André Brack

Centre de Biophysique Moléculaire CNRS,
Orléans, France

Keywords

Amino acids · Chirality · Comets · Impacts · Meteorites · Micrometeorites · Prebiotic compounds · Space experiments

Definition

The primitive Earth experienced a large spectrum of impactors ranging from the huge Mars-sized impactor which created the Moon to cosmic dust less than 1 μm in size. A great number of organic molecules, including amino acids, have been found in carbonaceous chondrites. Micrometeorite collection and analysis from the Greenland and Antarctic ice sheets suggest that the Earth accreted large amounts of extraterrestrial complex organic molecules. Intense bombardment probably caused some chemical reprocessing of the Earth's primitive atmosphere. Laboratory and space experiments support plausibility of the extraterrestrial delivery of organics to the primitive Earth.

Overview

Delivery of Extraterrestrial Organic Matter

Comets

Comets are the richest planetary objects in organic compounds known so far. Ground-based observations have detected hydrogen cyanide and formaldehyde in the coma of comets. In 1986, on board analyses performed by the two Russian missions Vega 1 and 2, as well as observations obtained by the European mission Giotto and the two Japanese missions Suisei and Sakigake, demonstrated that the Halley comet shows substantial amounts of organic material. On average, dust particles ejected

from the Comet Halley nucleus contain 14% of organic carbon by mass. About 30% of cometary grains are dominated by light elements C, H, O, and N, and 35% are close in composition to carbon-rich meteorites. The presence of organic molecules, such as purines, pyrimidines, and formaldehyde polymers, has also been inferred from the fragments analyzed by the Giotto Picca and Vega Puma mass spectrometers. However, there was no direct identification of the complex organic molecules probably present in the cosmic dust grains and in the cometary nucleus. Many chemical species of interest for exobiology have been detected in Comet Hyakutake in 1996, including ammonia, methane, acetylene (ethyne), acetonitrile (methyl cyanide), and hydrogen isocyanide. In addition, the study of the Hale-Bopp comet in 1997 led to the detection of methane, acetylene, formic acid, acetonitrile, hydrogen isocyanide, isocyanic acid, cyanoacetylene, formamide, and thioformaldehyde.

The Stardust mission collected samples of Comet Wild 2 and returned them to Earth in January 2006 for laboratory analysis. Unexpectedly, most of the comet's rocky matter formed inside the solar system at extremely high temperature. The grains contain organic functions (alcohol, ketone, aldehyde carboxylic acids, amides, and nitrile). The protein-building amino acid glycine has also been discovered.

Comets orbit on unstable trajectories and sometimes collide with planets. The collision of Comet Shoemaker-Levy 9 with Jupiter in July 1994 gave a recent example of such events. Such collisions were probably more frequent 4 billion years ago, the comets orbiting around the Sun being more numerous. Comets may therefore be an important source of organic molecules for the primitive Earth (Ehrenfreund and Charnley 2000; Despois and Cottin 2005). However, it is unlikely that whole comets could have safely delivered organics to Earth. They exploded either while entering the atmosphere or when impacting Earth's surface.

The European Rosetta probe launched in March 2004 to comet 67P / Churyumov-Gerasimenko reached its target in August 2014, after a journey of 7 billion kilometers. The probe detected glycine in the cometary tail (Altwegg

et al. 2016), confirming the Stardust results and the presence of complex carbonaceous matter similar to the insoluble organic matter present in carbonaceous meteorites. The lander, *Philae*, landed on the comet in November 2014, bouncing twice. During the first rebound, the probe was able to analyze the ice splashes. Sixteen organic compounds were identified (Goesmann et al. 2015).

Meteorites

Carbonaceous chondrites delivered organic materials to the early Earth. They contain from 1.5% to 4% of carbon, for the most part as organic materials. One hundred kilograms of the Murchison meteorite, a CM2-type carbonaceous chondrite that fell in Australia in 1969, has been extensively analyzed (Pizzarello 2007; Pizzarello and Shock 2010; Glavin et al. 2021). Murchison organic materials are generally classified according to their solubility in water and organic solvents. Insoluble and soluble components represent, respectively, 70% and 30% of total carbon components. The insoluble organic material is referred as kerogen-like, a poorly identified insoluble macromolecular material of complex composition with average elemental abundances $C_{100}H_{46}N_{10}O_{15}S_{4.5}$. NMR, IR, and pyrolysis analyses suggest the presence of aromatic ring clusters bridged by aliphatic chains, with peripheral branching and functional groups. The insoluble organic material releases a variety of aromatic and heteroatomic hydrocarbons as well as a suite of alkyl dicarboxylic acids up to C_{18} chain length under conditions similar to those of hydrothermal vents (Yabuta et al. 2007).

The soluble organic compounds of the Murchison meteorite represent a diverse and abundant group of organics that vary from small water-soluble compounds such as amino acids and polyols up to 30 carbon-long hydrocarbons. This diversity has been analyzed in considerable detail for the amino acids (Burton et al. 2012). The total number of detected meteoritic amino acid types is now about one hundred. All the possible α -amino alkylamino acids up to seven carbon atoms were identified as well as large abundances of N-substituted, cyclic, β -, γ -, δ -, and ϵ -amino acids. Eight protein-building amino acids

(glycine, alanine, proline, leucine, isoleucine, valine, aspartic acid, and glutamic acid) have been found. Nucleic acid bases, purines and pyrimidines, have also been found in the Murchison meteorite (Stoks and Schwartz 1982). Ribose was recently identified in the soluble organic matter of carbonaceous chondrites (Furukawa et al. 2019). Vesicle-forming fatty acids have been extracted from different carbonaceous meteorites (Yuen and Kvenvolden 1973; Deamer 1985, 1998).

A combination of high-resolution analytical methods, composed of organic structural spectroscopy FTICR/MS, UPLC-QTOF-MS, and NMR, applied to the organic fraction of Murchison extracted under mild conditions allowed to extend its Indigenous chemical diversity to tens of thousands of different molecular compositions and likely millions of diverse structures (Schmitt-Kopplin et al. 2010; Hertkorn et al. 2015).

Most of the amino acids detected in carbonaceous chondrites are chiral but present as racemic, i.e., L- and D-enantiomers are present in equal proportions. However, Cronin and Pizzarello (1997) found L-enantiomer excesses in six α -methyl- α -amino alkanolic acids from the Murchison (2.8–9.2%) and Murray (1.0–6.0%) carbonaceous chondrites. An enantiomeric excess, up to 18%, has been measured for isovaline (2-methyl-2-aminobutyric acid). These amino acids (isovaline, 2-amino-2,3-dimethylpentanoic, α -methyl norvaline, α -methyl valine, and α -methyl norleucine) are either unknown or rare in the terrestrial biosphere and cannot therefore be attributed to terrestrial contamination (Pizzarello 2007). In addition, the indigeneity of D- and L-isovaline enantiomers is supported by carbon and hydrogen isotopic data (Pizzarello et al. 2003; Pizzarello and Huang 2005).

Several organic and inorganic phases of the carbonaceous chondrite matrix were separated and subjected to the Soai reaction, i.e., the addition reaction of i -Pr₂Zn to pyrimidine-5-carbaldehyde. Asymmetric autocatalysis with amplification of chirality gave pyrimidyl alkanol with enantiomeric excesses of detectable level. The asymmetry resides in powders after extraction with water and solvents as well as in the

insoluble organic material obtained after demineralization. Asymmetry is not found any longer in the insoluble organic matter after hydrothermal treatment and in meteorite powders from which all organics had been removed (Kawasaki et al. 2006).

The meteoritic enantiomeric excesses may help to understand the emergence of homochiral (one-handed) life. Each amino acid, with the exception of glycine, exists in at least two enantiomeric forms, L and D, but proteins use only L ones. Proteins adopt asymmetrical rigid geometries, α -helices and β -sheets, which play a key role in their catalytic activity. Homochirality is now believed to be not only a consequence of life, but also a prerequisite for life (Brandenburg 2021), because stereoregular structures such as protein β -sheets, for example, do not form with mixtures of monomers of both handednesses. The use of one-handed biomonomers also sharpens the sequence information of the biopolymers. For a polymer made of n units, the number of sequence combinations is 2^n when the system uses only homochiral monomers. Taking into account the fact that enzyme chains are generally made of hundreds of monomers, the tremendous gain in simplicity offered by the use of monomers restricted to one handedness is self-evident. The enantiomeric excess of amino acids found in the Murchison meteorite may result from the processing of the organic mantles of interstellar grains by circularly polarized synchrotron radiation from a neutron star remnant of a supernova (Bonner 1991).

Strong infrared circular polarization, resulting from dust scattering in reflection nebulae in the Orion OMC-1 star-formation region, has been observed (Bailey et al. 1998). Circular polarization at shorter wavelengths might have been important in inducing chiral asymmetry in interstellar organic molecules that could be subsequently delivered to the early Earth (Bailey 2001).

The discovery of a large number of meteorites since 1969 has provided new opportunities to search for organic compounds in CM type carbonaceous chondrites (Pizzarello et al. 2001; Glavin et al. 2006; Pizzarello and Shock 2010) as well as in Renazzo-type (CR) chondrites found in

Antarctica with enantiomeric excesses of up to 60% (Pizzarello et al. 2012).

Micrometeorites

Interplanetary dust particle collections in Greenland and Antarctic ice sheets (Maurette 1998, 2006) show that the Earth captures interplanetary dust as micrometeorites at a rate of about 20,000 tons per year. Micrometeorites are relevant not only for planetary science and astrophysics as they help understand the composition of the Solar System but also for exobiology. About 99% of this mass is carried by micrometeorites in the 50–500 μm size range. This value is about 2000 times higher than the most reliable estimate of the meteorite flux, i.e., about 10 tons per year. This amazing dominance of micrometeorites already suggests their possible role in delivering organics to the early Earth 4.2 to 3.9 Ga ago when the micrometeorite flux was probably several orders of magnitude higher. Antarctic micrometeorite flux measurements suggest that a huge mass ($\sim 5 \times 10^{24}$ g) of micrometeorites was accreted by the Earth during the first ~ 300 Ma of the postlunar period.

At least ~ 20 wt. % of the micrometeorites survive unmelted after atmospheric entry. As their kerogen fraction represents about 2.5 wt. % of carbon, this amounts to a total mass of kerogen of $\sim 2.5 \times 10^{22}$ g on the early Earth surface equivalent to a ~ 30 -m-thick global layer (Maurette and Brack 2006). This delivery represents more carbon than that present in biomass in the present terrestrial biosphere (10^{18} g). α -Amino isobutyric acid has been identified in Antarctic micrometeorites (Brinton et al. 1998; Matrajt et al. 2004). These grains also contain a high proportion of metallic sulfides, oxides, and clay minerals, a rich variety of inorganic catalysts which could have promoted the reactions of the carbonaceous material which led to the origin of life. Analysis of the dust grains collected by the Cosmic Dust mission supports a cometary origin for the micrometeorites collected in Antarctica.

A collection of CONCORDIA Antarctic micrometeorites recovered from ultraclean snow close to Dome C provided the most unbiased collection of large cosmic dust available. Many

similarities can be found between Antarctic micrometeorites and Wild 2 samples, in terms of chemical, mineralogical, and isotopic compositions, and in the structure and composition of their carbonaceous matter (Dobrica et al. 2013).

Basic Methodology

Laboratory and Space Experiments Supporting Extraterrestrial Delivery

Synthesis

Ultraviolet irradiation of dust grains in the interstellar medium results in the formation of complex organic molecules. The interstellar dust particles are assumed to be composed of silicate grains surrounded by ices of different molecules, including carbon-containing molecules. Ices of H_2O , CO_2 , CO , CH_3OH , and NH_3 were deposited at 12 K under a pressure of 10^{-7} mbar and irradiated with electromagnetic radiation representative of the interstellar medium. The solid layer that developed on the solid surface was analyzed by enantioselective gas chromatography and mass spectrometry GC-MS. After the analytical steps of extraction, hydrolysis, and derivatization, 16 amino acids, including 6 protein amino acids, were identified in the simulated ice mantle of interstellar dust particles (Munoz Caro et al. 2002). These amino acid identifications confirmed the preliminary amino acid formation obtained by Mayo Greenberg (Briggs et al. 1992). The chiral amino acids were identified as being totally racemic. Parallel experiments performed with ^{13}C -containing substitutes definitely exclude contamination by biological amino acids. The results strongly suggest that amino acids are readily formed in interstellar space. Irradiation experiments, run with H_2O , NH_3 , CH_3OH , and HCN , produced only 3 amino acids, glycine, alanine, and serine (Bernstein et al. 2002).

Vacuum UV photo-irradiation of simpler ices containing H_2O , CH_3OH , and NH_3 led to the production of hydantoin, 2,4-imidazolidinedione (De Marcellus et al. 2011), a molecule suspected to play an important role in the formation of oligopeptides. Hydantoin is known to form

under extraterrestrial conditions, since it has been detected in the soluble organic fraction of primitive carbonaceous meteorites (Cooper and Cronin 1995; Shimoyama and Ogasawara 2002). Glycine and alanine were dominantly formed when 5-substituted hydantoins were UV-irradiated and hydrolyzed (Sarker et al. 2013).

Irradiation of ice mixtures of $\text{H}_2\text{O}/^{13}\text{CH}_3\text{OH}/\text{NH}_3$ by circularly polarized light provided 16 distinct amino acids. The L-enantiomeric excesses were measured in five of them: α -alanine, 2,3-diaminopropionic acid, 2-aminobutyric acid, valine, and norvaline, with values ranging from $eeL = -0.20\% \pm 0.14\%$ to $eeL = -2.54\% \pm 0.28\%$. The results support an astrophysical scenario in which the solar system formed in a high-mass star-forming region where icy grains were irradiated during the protoplanetary phase by an external source of circularly polarized light of a given helicity, inducing a stereo-specific photochemistry (Modica et al. 2014).

Key Research Findings

The collection and analysis of micrometeorites suggests their role in delivering complex organics to the early Earth 4.3 to 3.5 Ga ago when life is considered to have emerged.

Applications

Space Travel

To estimate whether different amino acids could survive a trip in space embedded in micrometeorites, a suite of amino acids like those detected in the Murchison meteorite was exposed to space conditions in Earth orbit on board the unmanned Russian satellites FOTON 8 and 11, free and associated with clay minerals. Free exposed aspartic acid and glutamic acid were partially destroyed during exposure to solar UV. However, decomposition was prevented when the amino acids were embedded in clays (Barbier et al. 1998). Amino acids have also been subjected to solar radiation outside the MIR space station for 97 days. The samples were

exposed in free form and associated with different ground mineral supports to mimic micrometeorites, i.e., montmorillonite clay, powdered basalt, and powdered Allende meteorite. In the absence of mineral protection, about half of the amino acids were destroyed by UV radiation. The main photochemical degradation process was the decarboxylation of the carboxylic acid function. Significant protection from solar radiation was observed when the thickness of the added minerals was 4–5 μm or greater (Boillot et al. 2002).

The protective action of meteorite powder was confirmed with the 18-month exposure experiment PROCESS using the EXPOSE-E facility mounted on the European Technology Exposure Facility (EuTEF) platform on board the International Space Station. The amino acids exposed in the free form were degraded by more than 40% while more than 80% of the compounds associated with meteorite powder were preserved (Cottin et al. 2012).

Impact Shock Chemistry

Intense bombardment probably caused some chemical reprocessing of the Earth's primitive atmosphere by impact shock chemistry. An indication of the number and timing of the impacts onto the early Earth can be obtained by comparison with the cratering record of the Moon, which records impacts from the earliest history of the solar system (Ryder 2003). Because of the larger size of the Earth and its greater gravitational pull, about 20 times as many impacts would have occurred on the early Earth as on the Moon. Computer modeling of the impact shock chemistry shows that the nature of the atmosphere strongly influences the shock products (Fegley Jr et al. 1986). A neutral CO_2 -rich atmosphere produces CO , O_2 , H_2 , and NO while a reducing CO -rich atmosphere yields primarily CO_2 , H_2 , CH_4 , HCN , NH_3 , and H_2CO . The last three compounds are particularly interesting for prebiotic chemistry since they can lead to amino acids via the Strecker synthesis. However, it is difficult to know if such an atmosphere really existed. In laboratory experiments, a gas mixture of methane, ammonia, and water subjected to shock heating followed by a rapid thermal quenching yielded the amino acids

glycine, alanine, valine, and leucine (Bar-Nun et al. 1970). Here again, the gas mixture used does not represent a realistic primitive atmosphere, which was dominated by CO₂. Laboratory simulations of shocks were also run with a high-energy laser. CH₄-containing mixtures generated hydrogen cyanide and acetylene, but no organics could be obtained with CO₂-rich mixtures (McKay and Borucki 1997).

Large impacts could also have promoted some fine ejecta particle chemistry. For 10–15 km-sized impactors, modeling (Lyons and Vasavada 1999) has shown that 100 μm fine ejecta particles would have been heated to about 200 °C during reentry in a 0.3 bar CO₂ atmosphere. For impactors larger than 20 km, the heat experienced by the fines would destroy all organics by pyrolysis or combustion.

Furukawa and colleagues (Furukawa et al. 2009) investigated whether, rather than just transporting amino acids, meteorite impacts could themselves synthesize organic compounds. The group subjected a mixture of solid carbon, iron, nickel, water, and nitrogen to high-velocity impacts in a propellant gun. This experiment simulated the chemistry experienced by ordinary chondrites when hitting the Earth's early oceans. They recovered several organic molecules after the impact, including complex molecules such as fatty acids and amines. Glycine, the simplest protein-building amino acid, was formed when the starting material contained ammonia, which is believed to have been formed in prior impacts on the early Earth. To avoid potential contamination by biological materials, the authors used solid carbon composed only of ¹³C. Subsequent analyses of the recovered organic products showed that they were all formed with the ¹³C, ruling out the presence of any naturally formed biological contaminants, which would have been enriched in ¹²C.

The effects of impact shock on amino acids and a peptide in artificial meteorites composed of saponite clay were investigated (Bertrand et al. 2009). The samples were subjected to pressures ranging from 12 to 28.9 GPa, which simulated impact velocities of 2.4–5.8 km/s. Volatilization was determined by weight loss measurement, and

the amino acid and peptide response was analyzed by gas chromatography–mass spectrometry. At the highest shock pressures, amino acids with an alkyl side chain were more resistant than those with functional side chains. Impact shock may therefore act as a selective filter to the delivery of extraterrestrial amino acids via carbonaceous chondrites. The peptide cleaved into its two primary amino acids. Some chiral amino acids experienced partial racemization during the course of the experiment, suggesting that the enantiomeric excesses measured in carbonaceous chondrites are probably underevaluated.

Future Directions

Meteorite and micrometeorite collection and analysis as well as laboratory and space experiments strongly support an extraterrestrial pathway for the delivery of organic molecules at the time that life originated. The building blocks of life or their precursors could have been brought in by small impactors, possibly supplemented by prebiotic molecules formed in the atmosphere and oceans by meteorite impacts.

Keywords

Extremophiles

Synonyms

[Extreme field sites](#)

Definition

An extreme ► [environment](#) is a habitat characterized by harsh environmental conditions, beyond the optimal range for the development of humans, for example, pH 2 or 11, -20°C or 113°C , saturating salt concentrations, high radiation, and 200 bars of pressure, among others. Basically, these are all inhospitable conditions for life. By definition, the organisms that are able to live in extreme environments are known as ► [extremophiles](#). Not so long ago it was thought that life could not occur under extreme conditions. In the 1960s, Professor Thomas D. Brock, from Wisconsin-Madison University, isolated and described the first organisms from Yellowstone National Park, USA. This organism, *Thermus aquaticus*, is capable of growing at temperatures higher than 70°C . Its DNA polymerase has been widely applied in molecular biology as it is the base of the polymerase chain reaction (PCR) based on the thermophilic properties of the micro-organism that produces it. *Sulfolobus acidocaldarius*, growing at temperatures higher than 85°C , was also isolated and characterized

at the same time and was the first characterized hyperthermophilic archaea.

History

In 1974, R. D. MacElroy published “Some comments on the evolution of extremophiles” (Biosystems 6: 74–75); this was the first time the term ► “**extremophile**” was used.

Overview

Depending on the extreme physicochemical conditions that characterize the extreme environments, they are classified as follows:

Extreme temperature. Two types of extreme ecosystems can be described: cold and hot. Extremely cold environments are those with temperatures consistently below 5 °C. They can be found in deep ocean niches, at the peaks of high mountains, or in the polar regions. Organisms living in extreme cold environments are known as psychrophiles. Some of them, such as the organisms found in Vostok Lake are able to live at –20 °C.

Extremely hot environments are characterized by regular temperatures higher than 45 °C. These environments are typically influenced by geothermal activity as geysers and fumaroles of continental volcanic areas or deep-sea vents. Typical extreme hot environments can be found in the geothermal areas of Yellowstone and in some locations of Iceland or Kamchatka. The organisms in these environments are thermophiles. Some microorganisms are able to develop at temperatures higher than 80 °C, and they are called hyperthermophiles. These organisms are associated with hydrothermal activities.

Extreme pH. Extreme environments can be classified as acidic or alkaline according to their pH.

Extreme acidic environments are natural habitats in which the pH is below 5. Some

examples of extreme acidic environments are Río Tinto (Iberian Pyritic Belt, SW Spain), mean pH 2.3, or Iron Mountain in California (USA) where the pH in some areas is below 1. Organisms developing in these acidic environments are known as acidophiles.

Extreme alkaline environments are those with a pH above 9. Examples of this type of environment are the soda lake of Magadi, Mono Lake, or salt pans. Organisms found in these environments are called alkaliphiles.

Extreme ionic strength. Hypersaline environments have an ionic concentration higher than of seawater, >3.5%. Typical hypersaline environments are the Dead Sea (Israel), the Great Salt Lake (USA), or the salterns of Santa Pola (Spain). Organisms able to grow at high ionic strength are known as halophiles. Most alkaliphilic organisms are also halophiles.

Extreme pressure environments are those under extreme hydrostatic or litho pressure, such as aquatic habitats at depths of 2000 m or more or deep-subsurface ecosystems. Organisms living under high pressure can be classified as barotolerant if they can tolerate high pressure or barophilic if they depend on pressure to grow.

High-radiation environments are those habitats exposed to abnormally high radiation doses, including ultraviolet or infrared radiation, like deserts, the top of high mountains, or on the surface of the International Space Station.

Xeric environments are extreme dry habitats with seriously limited water, an extremely important element for life. Cold and hot deserts are some examples of these extreme environments.

Oligotrophic environments are extreme ecosystems that offer low levels of nutrients to sustain life. Oligotrophic environments include deep oceanic sediments, polar ice, or the deep subsurface.

Definition

Life is influenced by physical parameters such as temperature, pH, salinity, pressure, etc. Extremophiles are organisms that thrive in ecosystems where at least one physical parameter is close to the known limits of life with respect to this parameter. While some organisms may temporarily survive harsh conditions by forming resistant stages (spores) or through specific mechanisms (heavy metal resistance), true extremophiles require these conditions. For instance, hyperthermophiles successfully complete their life cycle at optimal temperatures above 80 °C and commonly do not grow at all below 60–70 °C.

History

Before 1965, the upper temperature limit known for life was about 73 °C. When Thomas Brock discovered thermophilic bacterium *Thermus aquaticus* in the Octopus Hot Spring in Yellowstone National Park (USA), the research on extremophiles truly began. *Thermus aquaticus* lives in temperatures ranging from 50 °C to 80 °C. Since then, many alkaliphiles, acidophiles, halophiles, and piezophiles have been discovered and studied for their taxonomy, ► [phylogeny](#), physiology, biochemistry, molecular biology, genetics, and applications. According to Gerday and Glansdorff (2007), “For biologists, the realization that many forms of life are actually confined to environments that are severely hostile by human standards will remain one of the most significant achievements of the second half of the twentieth century.” But “the questions raised by the molecular basis and the emergence of different forms of extremophily are not only deep and varied, but, not surprisingly, many remain controversial.” At the beginning of the twenty-first century, research on extremophiles is still an open field.

Overview

Living organisms exposed to severe environmental conditions are frequently named “extremophiles.” However, they belong to different categories. Some organisms resist hostile conditions (elevated temperatures, ► [desiccation](#), etc.) by forming sophisticated resistant and dormant stages such as the spores produced by several Gram-positive ► [bacteria](#). Such forms can survive for very long periods (millions of years in the view of some authors) and then produce growing cells after environmental conditions become favorable. Other organisms can temporarily resist toxic compounds such as heavy metals or ionizing radiation, through specific mechanisms. But these two categories do not require such hostile conditions for growth. A third category truly deserves the name extremophile: These organisms require environmental conditions hostile for most

of the other organisms to complete their whole life cycle: very low temperatures for psychrophiles, very high temperature for thermophiles, very low pH for acidophiles, very high pH for alkaliphiles, elevated salt concentrations for halophiles, or elevated hydrostatic pressure for piezophiles.

Basic Methodology

Since extremophiles thrive in environments hostile for many organisms and particularly human beings, the main difficulty encountered during the study of extremophiles is access to extreme environments. Whereas access to continental hot springs (acidic or alkaline), glaciers, salt mines, or evaporating ponds only requires specific clothing and caution, access to the deep-sea hydrothermal vents, where psychro-piezophiles or hyperthermophiles are found, is much more complex. In this case, sophisticated underwater vehicles (manned submersibles or remotely operated vehicles (ROV)) are needed. The next challenge after sampling is the preservation of samples for further cultivation in the laboratory. Many extremophiles are strictly anaerobic and require anaerobic-reduced conditions during preservation at low temperature. Probably many obligate piezophiles do not survive sampling procedures since it is very difficult (and very expensive) to deploy pressure-retaining samplers. Psychrophiles are very sensitive to moderate temperature (room temperature), and all the glassware and reagents used must be precooled.

Finally, cultivation of extremophiles requires mimicking the main environmental conditions of their environments in the laboratory. The difficulties of growing lithoautotrophic organisms even under non-extreme conditions are great, but the most difficult to grow are probably piezophiles which require high-pressure bioreactors.

Key Research Findings

Thermophiles

Thermophiles are organisms that grow optimally above 60 °C, and hyperthermophiles grow

optimally above 80 °C. The most thermophilic and hyperthermophilic organisms are prokaryotes and belong to the Bacteria, but essentially ► **Archaea** domains. They have been isolated from diverse hot environments such as continental hot springs, oil reservoirs, or deep-sea hydrothermal vents. According to their natural environments, many of them combine thermophily with acidophily or piezophily. They have representatives in various metabolic types: They may be aerobes, microaerophiles or anaerobes, and chemoorganotrophs or chemolithoautotrophs. As a whole, they may use a variety of electron donors and acceptors. Many of them have very short generation times, about 30 min under optimal conditions.

The most thermophilic organism is an Archaea, *Pyrolobus fumarii*, isolated from a deep-sea hydrothermal vent. *P. fumarii* grows in a temperature range of 90–113 °C, with an optimum at 106 °C. It can survive an exposure of 24 h in an autoclave. Growth at 121 °C of an iron reducer organism, also isolated from a deep-sea hydrothermal vent, has been reported. However, the strain has not been published as a novel organism nor deposited in type culture collections, and this result is still to be confirmed. Thermophiles may also harbor viruses that live in the same environmental conditions, but their life cycle and relationships with their hosts are still unknown.

Psychrophiles

Psychrophiles are cold-adapted organisms that grow optimally at temperatures around 15 °C and never grow beyond 20 °C. Their minimum temperature for growth can be below 0 °C. Organisms that can grow at low temperatures but also beyond 20 °C are named psychrotolerant. The lower temperature limit for growth is not easy to determine, since very low temperatures (–80 °C in deep freezer, –196 °C in liquid nitrogen) are used for long-term preservation of both prokaryotic and eukaryotic cells. However, growth of bacterial cells at temperatures as low as –10 to –12 °C, and metabolic activity at –20 °C in concentrated brines have been reported. Psychrophiles not only inhabit the deep cold oceans but also polar

regions, high mountains, glaciers, etc. They almost certainly belong to many phylogenetic lineages, but most of the cultivated species belong to the Bacteria domain, particularly the proteobacteria.

Halophiles

Halophiles are organisms living in salty environments such as the oceans. However, many environments are much more saline and salt concentrations can reach 340 g/l. Typical settings are salt lakes, solar salterns, underground deposits of rock salts, but also salted food products. Organisms living optimally in these highly salted environments are named extreme halophiles. Several salty environments also have a high pH and a rather high temperature, and consequently their inhabitants are polyextremophilic. Extreme halophiles (growing in salt concentrations above 100 g/l) are found in the three domains of life, but most of them are prokaryotes, and the most extreme belong to the Archaea domain. Two lineages of halobacteriales and certain methanogens are included. The halobacteriales are heterotrophic organisms that produce red pigments, some of which (bacteriorhodopsin, halorhodopsin) are involved in light-driven proton and chloride pumps.

Acidophiles

Acidophilic organisms grow optimally at pH below 7, but there is a distinction between moderate acidophiles that grow at pH from 5 to 3 and extreme acidophiles that grow at pH below 3. Acidophiles are found in natural acidic springs in volcanic areas, but also in sulfide ore or coal deposits. Acidophiles exist in the three domains of life, and several yeasts, fungi, and protozoa grow at pH below 2. Among the prokaryotes, acidophiles are very diversified from a metabolic point of view, and both heterotrophs and autotrophs are found. Many acidophiles oxidize sulfides and sulfur, using oxygen as an electron acceptor. Since ferrous iron is stable at low pH under aerobic conditions, many acidophiles are also iron oxidizers. The most acidophilic organism on Earth is the Archaea *Picrophilus*, which has an optimal pH of 0.7 and still grows at pH 0.

Alkaliphiles

Alkaliphiles are commonly divided into two categories: the alkali-tolerant organisms can grow at alkaline pH (8–9), but their optimum is around neutral pH. True alkaliphiles can grow at pH above 10 and/or grow equally well or better (rate, yield) at pH above 9. Some are facultative ► [alkaliphile](#); true alkaliphiles cannot grow at pH below 8. Alkaliphiles occur in natural high-pH environments such as ► [soda lakes](#), underground alkaline waters, and hidden small niches such as insect guts. They are also found in artificial environments such as waste of food-processing industries. They have representatives in the three domains of life, but are most abundant in several lineages of the Bacteria domain, particularly the low G + C Gram-positive bacteria of the genus *Bacillus*. Some alkaliphiles also exhibit slight thermophilic properties.

Piezophiles

Piezophiles were first named barophiles, from the Greek word for weight. Piezophile is more appropriate because it comes from the Greek word for pressure. Piezophiles thrive in environments exposed to elevated hydrostatic pressure. Piezotolerant, piezophilic, and obligate piezophilic exist. The latter requires pressures above 1 bar to grow. They are found in habitats such as deep oceans, deep aquifers, oil fields, and deep sediments. The first obligate piezophile was isolated from a dead crustacean amphipod collected at the Mariana Trench (10,470 m depth). It is an aerobic heterotrophic bacterium that grows optimally at 2 °C (it is also a ► [psychrophile](#)), under 690 bars (or 69 Mpa) with a generation time of 25 h. When exposed to hydrostatic pressure, this organism loses its ability to form colonies and dies. Piezophilic characteristics are also known in some hyperthermophiles isolated from deep-sea hydrothermal vents. *Pyrococcus yayanosii* strain CH1 grows in a temperature range of 80–105 °C, with an optimum at 98 °C, under an optimal hydrostatic pressure of 52 Mpa. Its pressure range extends from 20 to at least 120 Mpa. At all temperatures, no growth was observed for pressures below 20 Mpa.

Applications

Extremophiles are able to grow under extreme conditions of temperature, pH, salt concentration, and pressure. Consequently, the metabolic pathways and enzymes involved in these pathways are also extremophilic and are named extremozymes. Extremozymes have two general properties: they are active under extreme conditions, but are also very stable. For those reasons they represent a powerful tool for industrial biotransformations, carried out under harsh conditions. Most of them come from thermophilic and hyperthermophilic organisms.

Many extremozymes are involved in starch processing: alpha- and beta-amylases, glucoamylases, alpha-glucosidase, pullulanase, CgTases, branching enzymes, and amylomaltases. There are extremozymes that can be used for other transformations such as cellulose, xylan, chitin, pectin-degrading enzymes, proteolytic enzymes, lipases and esterases, alcohol dehydrogenases, glucose and arabinose isomerases, nitrile-degrading enzymes, etc. Modern DNA technology also utilizes extremozymes from thermophiles. The most famous example is the thermostable *Taq* polymerase, from the thermophilic bacterium *Thermus aquaticus*. This polymerase permitted the revolution in DNS technology through the PCR (polymerase chain reaction) technology. Other enzymes such as ligases, nucleases, and topoisomerases are also commonly used.

Extremophiles can also be used as whole-cell biocatalysts for biomining, decontamination or bioremediation, and hydrogen production. Finally, biomolecules extracted from extremophiles such as proteins and peptides, biopolymers, compatible solutes, or lipids have a wide range of applications.

Future Directions

At the beginning of the twenty-first century, the world of extremophiles has revealed a variety of fascinating organisms, most of which are prokaryotes. However, despite the thousands of papers

that have been published on the subject, many questions remain.

Extremophiles thrive at the limits of the life on Earth, but what those limits are precisely is not yet fully understood, particularly for elevated temperatures and pressures. Although it is not possible to imagine an organism more acidophilic than *Picrophilus* (already at the low pH limit), it may be possible to find an organism that combines extreme acidophily with extreme thermophily and piezophily or any other combination. To discover such pluri-extremophiles, exploration of planet Earth for new biotopes must be continued. It was recently reported that living microorganisms exist in very deep (1600 m thickness) and old (110 million years) marine sediments. At this location, temperature was estimated to be only 80–100 °C. But the known temperature limit for life is 113 °C (perhaps more), and because temperature increases by only 30 °C per kilometer, life could occur at even greater depths.

Such organisms may also represent novel lineages and may use novel metabolic pathways or novel enzymes. For each of them, the cellular and molecular mechanisms of adaptation remain to be understood and may open a variety of potential applications.

By pushing the definition of the limits for life to ever greater extremes, biologists engaged in research on extremophiles will help develop novel hypotheses about the origin of life on Earth and its existence elsewhere.

[Faint young Sun problem](#)

Definition

The apparent contradiction between model calculations that indicate a dimmer young Sun and consequently mean below-freezing temperatures

at the Earth's surface and the geological evidence that early climates on Earth and Mars were mild if not hot and that liquid water was abundantly present on the other hand.

Overview

There is clear evidence for a mild climate on the young Earth and Mars, allowing liquid water – a prerequisite for the formation of life as we know it – to exist on the surface of both planets at ages of a few 100 Myr to 1 Gyr. Liquid water seems to have subsequently disappeared from the surface of Mars. However, detailed stellar evolutionary theory applied to the Sun during its main-sequence life indicates that it was fainter by about 30% when it arrived on the main sequence 4.6 billion years ago, and the radiative output increased only slowly in the next billion years. Both planetary surfaces would thus have been completely frozen. To solve this apparent paradox (Sagan and Mullen 1972), various hypotheses have been proposed although a conclusive answer is still outstanding. The most popular theory assumes higher admixtures of greenhouse gases in the atmospheres of Earth and Mars; such gases include carbon monoxide, ammonia, and methane (CO_2 , NH_3 , and CH_4 , respectively). A radically different hypothesis posits that the young Sun was not faint – it may rather have been brighter because it was more massive by a few percent. Direct evidence for the implied strong mass loss in the younger epochs of solar evolution is still outstanding. Further hypotheses assume a lower albedo due to less efficient cloud formation, for example, as a consequence of more efficient suppression of cosmic rays in the young solar system, or a smaller fractional area of land, or the lack of biologically induced cloud condensation nuclei. For a recent review of the subject and a summary of evidence for a warm early Earth with liquid surface water, see Feulner (2012).

Basic Methodology

The average, effective equilibrium temperature of a planetary surface in the absence of an

atmosphere follows from the energy balance between optical/near-infrared emission irradiating the planet and mid-infrared thermal radiation that is lost to space. The incoming power from the Sun is

$$P_{\text{in}} = \pi R^2 S (1 - A)$$

where $S = L_{\odot}/4\pi d^2 = 1366 \text{ W m}^{-2}$ is the solar constant (solar radiative energy flux at the distance d of the Earth, where $L_{\odot}$ is the solar luminosity), $A \approx 0.29$ is the Earth's Bond albedo (fraction of radiation that is reflected), and $R = 6378 \text{ km}$ is the Earth's radius. The power leaving from the Earth's atmosphere can be approximated as radiation from a blackbody surface with temperature T ,

$$P_{\text{out}} = 4\pi R^2 \varepsilon \sigma T^4$$

where $\sigma = 5.67 \times 10^{-8} \text{ W m}^{-2} \text{ K}^{-4}$ is the Stefan-Boltzmann constant and ε is the surface mid-infrared emissivity. Equating $P_{\text{in}} = P_{\text{out}}$ leads to

$$T^4 = \frac{S(1 - A)}{4\varepsilon\sigma}$$

With the above numbers and $\varepsilon \approx 0.9$ for solid rock (Sagan and Mullen 1972), $T \approx 260 \text{ K}$. For a planet surrounded by an atmosphere, the effective temperature can be raised owing to the presence of greenhouse gases. The latter are nearly transparent to incident optical and near-infrared light but strongly absorb reemitted thermal radiation in the mid-infrared. The equation for the mean surface temperature of the atmosphere can then be approximated by (e.g., Feulner 2012)

$$T^4 = \frac{S(1 - A)}{4\varepsilon\sigma} \left(1 + \frac{3\tau^*}{4} \right)$$

where τ^* is the column infrared gray opacity responsible for the warming by greenhouse gases.

Heat flow from the interior of the Earth is, in contrast, negligibly small (although it matters for maintaining plate tectonics; Feulner 2012 and references therein). Considering the greenhouse effect for a present-day atmosphere leads to a

somewhat elevated average temperature of 288 K (15 °C), in agreement with measurements (e.g., Sagan and Mullen 1972; Kasting and Catling 2003).

The total radiative output of the young Sun can be assessed from two sources: (1) The theory of stellar evolution indicates that the young Sun at a time when it started core hydrogen burning on the main sequence emitted 30% less electromagnetic radiation than at present (e.g., Sackmann and Boothroyd 2003). (2) The total luminosity of stars with known masses and ages can in principle be derived from observations; stellar masses and ages are, however, difficult to infer accurately.

Our knowledge of the early climate history of the Earth and other planets, in particular Mars, relies on geological evidence, such as (1) oxygen isotopes measured in Jack Hills zircons dated at 4.4–4.3 Ga, which suggested that parent rocks interacted with liquid water; (2) 3.8 Ga old sedimentary rocks from Isua (West Greenland) clearly deposited in aquatic environments; and (3) extensive outflow channels and valley networks in the Martian highlands. All of these pieces of evidence indicate mild climates and the presence of liquid

water on both young planets (Valley et al. 2002; Feulner 2012).

Key Research Findings

Assuming the same atmospheric composition for the Earth as today but a solar constant reduced by about 30%, calculations yield average atmospheric temperatures of about 260 K for the young Earth around 4 billion years ago. The temperature would have remained below the freezing point until 2 billion years ago (Sagan and Mullen 1972; Kasting and Catling 2003; Fig. 1). This clearly contradicts geological evidence for a significantly warmer early climate on Earth (e.g., Kasting and Toon 1989) and especially also on Mars. This contradiction is the essence of the faint young Sun paradox (FYSP).

Various hypotheses have been put forward addressing the FYSP but the solution remains inconclusive. We summarize the key points of the proposed solutions below. Considering the above equation for the atmospheric temperature, T , and the determining variables,

Faint Young Sun Paradox, Fig. 1 Illustration of the faint young Sun paradox for the Earth, in the context of the atmospheric greenhouse. The solid line depicts the solar luminosity relative to the present value (right y-axis); the lower dashed curve is the effective temperature of the Earth without atmosphere, and the upper dashed curve shows the calculated, mean global surface temperature affected by the

greenhouse (with fixed CO_2 mixing ratio and relative humidity). (From Kasting and Catling 2003, reprinted, with permission, from the Annual Review of Astronomy and Astrophysics, volume 41 © 2003 by Annual Reviews, www.annualreviews.org. Courtesy of J. Kasting; credit: Scientific American and Princeton University Press)

most potential solutions of the FYSP for the young Earth fall into the following categories: (i) an increased greenhouse effect (τ^*), (ii) a reduced albedo A , and (iii) an increased solar luminosity $L_\odot$. A smaller semimajor axis of the Earth's orbit (resulting in an increased solar flux S at Earth) or a significantly reduced emissivity ε are unlikely (Feulner 2012 and references therein.)

Different Atmospheric Composition: Greenhouses

The composition of the young atmospheres may have been different, allowing for much stronger greenhouses on Earth or Mars. Many authors have favored this hypothesis, although it faces its own problems. Larger amounts of CO_2 would strongly support the greenhouse together with water vapor (Kasting 1993). The required CO_2 level to keep liquid water oceans would be self-regulated by the carbonate-silicate cycle (e.g., Walker et al. 1981; Kasting and Catling 2003). Increased CO_2 levels would at the same time also prevent massive losses of N_2 under the influence of an enhanced early solar wind and enhanced extreme-ultraviolet radiation (Lichtenegger et al. 2010). There are, however, various geochemical and geological evidences against the required very massive CO_2 atmospheres, such as the absence of siderite in paleosols (Rye et al. 1995; Rosing et al. 2010, and references therein); a dense Martian CO_2 atmosphere would significantly enhance the Martian albedo, thus not raising the temperature sufficiently (Kasting 1991). Although these same clouds may also backscatter thermal radiation and therefore support the greenhouse mechanism (Forget and Pierrehumbert 1997), experiments suggest that this effect is too small to raise the temperatures above the freezing point (Glandorf et al. 2002). However, for a period around 2–2.5 Gyr ago, recent calculations indicate that a lower CO_2 content of 2.9 Mb partial pressure would have been sufficient to keep liquid water on the Earth's surface, and this pressure is in agreement with geological findings (von Paris et al. 2008).

Another leading candidate among greenhouse gases is ammonia (NH_3) which would be required

in only relatively small amounts. However, NH_3 dissociates rapidly if subject to solar UV radiation (Kuhn and Atreya 1979), but additional methane (CH_4) may produce a high-altitude haze of organic solids through photolysis, which shields ammonia sufficiently from UV dissociation (Sagan and Chyba 1997). Methane itself is an efficient greenhouse gas (Kasting 1997; Pavlov et al. 2000). But the mixing ratio of $\text{CH}_4:\text{CO}_2$ should stay below unity to avoid increased albedo due to haze formation and therefore an anti-greenhouse effect (McKay et al. 1999; Pavlov et al. 2001; Haqq-Misra et al. 2008), in turn requiring too high levels of CO_2 for a significant greenhouse. Haze is produced at even considerably lower $\text{CH}_4:\text{CO}_2$ mixing ratios (DeWitt et al. 2009). On the other hand, enhanced levels of H_2 suppress haze formation and this limits the anti-greenhouse effect, possibly resulting in a net greenhouse warming by CH_4+CO_2 (DeWitt et al. 2009). The presence of sufficiently high levels of H_2 remains to be demonstrated, however. Ethane (C_2H_6) and carbonyl sulfide (OCS) have been proposed as alternative efficient greenhouse gases in the young terrestrial atmosphere (Haqq-Misra et al. 2008; Ueno et al. 2009) although OCS itself, for example, is rapidly photodissociated (Domagal-Goldman et al. 2011).

Albedo Effects Due to Cloud Formation and Land Coverage

A much lower albedo, A , would allow T to rise. This explanation was initially deemed unlikely because the probably larger surface of the young Earth covered by ice would rather increase A (Sagan and Mullen 1972).

The albedo could, however, have been lower due to a lower cloud coverage in particular in cooler environments (Rossow et al. 1982; Charlson et al. 1987; Rosing et al. 2010). Detailed studies of clouds show two competing effects (Goldblatt and Zahnle 2011a): low-lying clouds reflect solar radiation, thus increasing the albedo; in contrast, high clouds, in particular ice-crystal cirrus clouds, add to atmospheric greenhouse warming, potentially sufficient to solve the FYSP (Rondanelli and Lindzen 2010) although full coverage by an unrealistically thick and cold

cloud cover would be required (Goldblatt and Zahnle 2011a).

There is some evidence that elevated cosmic-ray fluxes have a cooling effect on the Earth's atmosphere because they ionize tropospheric layers, and charged ion clusters lead to condensation nuclei that form reflective clouds (Shaviv 2003). But because the ionized wind of the young Sun is thought to have been much stronger than today, the cosmic-ray flux reaching the inner solar system was more strongly suppressed, therefore suppressing cloud formation in the young Earth's atmosphere and in turn leading to a warmer climate (Shaviv 2003). This model has been observationally refuted, however (e.g., Bailer-Jones 2009 and references therein).

A lower surface albedo may also be the result of the suggested smaller continental area in early epochs although feedback on cloud coverage may result in opposite trends. The absence of cloud condensation nuclei induced biologically (Charlson et al. 1987) also decreases the albedo. Considering these effects and claiming less reflective clouds because of larger cloud droplets (because of fewer biogenically induced condensation nuclei), Rosing et al. (2010) inferred a clement climate for the young Earth without the need for high amounts of greenhouse gases although this solution was again questioned (Goldblatt and Zahnle 2011b).

The amount of ice coverage and thus effects on the energy balance can be influenced by variations in the Earth's axial tilt or its rotation period (slowly increasing with time due to the Moon's tidal forces). Models for these effects are inconclusive (Feulner 2012 and references therein).

A Brighter Young Sun

A radical remedy of the FYSP would be a young Sun that was significantly more massive than at present, losing the excess mass during its main-sequence life in an enhanced ionized wind (Whitmire et al. 1995; Sackmann and Boothroyd 2003). The bolometric luminosity (i.e., the luminosity integrated over the electromagnetic spectrum) of main-sequence stars scales approximately with stellar mass to the third power; further, the radius of the Earth's orbit

would have been smaller for a more massive Sun (the orbital radius scales inversely with the solar mass). Both effects combine to a scaling of the received flux with the fifth power of the solar mass.

Constraints on this model come from the requirement that the young Martian atmosphere was warm enough to maintain water in liquid form, but the Earth's atmospheric temperature was moderate enough to prevent loss of the water oceans in a runaway greenhouse. The appropriate mass range for the young Sun was thus $1.03 M_{\odot}$ to $1.07 M_{\odot}$. Corresponding solar models are in acceptable agreement with helioseismology results (Sackmann and Boothroyd 2003).

The observational evidence is presently unclear. Upper limits to the ionized-wind mass-loss rates deduced from radio observations of young solar analogs are marginally compatible with the "bright young Sun" requirement, indicating a maximum zero-age main-sequence (ZAMS) solar mass of $1.06 M_{\odot}$ (Gaidos et al. 2000). Indirect observations suggest a smaller mass loss. If the solar wind had been constant throughout the Sun's main-sequence life, then, including the losses from conversion of matter to energy in the hydrogen-burning core, a total mass loss of only $0.0004 M_{\odot}$ would have been achieved, which alters the solar radiative output insignificantly. However, observations of "hydrogen walls" in the astrospheres of neighboring solar-like stars support an increased wind-mass loss in younger stars (Wood et al. 2005). A power-law trend extrapolated back to the ZAMS indicates a total mass loss of order $0.01 M_{\odot}$, but some evidence shows that the mass-loss rate was suppressed during the youngest epochs; including this latter effect leads to a total mass loss of only $0.003 M_{\odot}$ (Minton and Malhotra 2007), again too little for a significant luminosity effect. The Wood et al. method has its own limitations, however, and strongly depends on numerical modeling of the complex interaction between magnetic stellar winds and the magnetized interstellar medium (ISM). A possibility is non-isotropic stellar winds that would interact differently with the ISM. The hydrogen wall observations also require

the presence of a neutral ISM component around the astrospheres. The hypothesis of a bright young Sun therefore remains inconclusive.

Faint Young Sun Problem

► Faint Young Sun Paradox

False Negative

John Lee Grenfell
 Institut für Planetenforschung, Extrasolare
 Planeten und Atmosphären, Deutsches Zentrum
 für Luft- und Raumfahrt (DLR), Berlin, Germany

Definition

In general, a “false negative” refers to the result of an experiment or test which fails to support a particular hypothesis, even though the hypothesis is in fact correct. In an astrobiological context, “false negative” refers to the absence of a detectable life signal even though life is in fact present.

Overview

It is convenient to consider three cases when searching for evidence of life. First is the case where (intelligent) life does not wish to be found and makes efforts to suppress its remote **biosignatures** (e.g., by blocking its

electromagnetic emissions into space or by engineering its atmosphere to suppress the buildup of biosignature gases). Second is the case where physical or/and chemical processes interfere, degrade, or hide (spectral) biosignature(s), e.g., via the presence of an optically thick cloud layer which traps radiation below the cloud base or via photochemical processes which remove biosignature gases in situ in the atmosphere, e.g., via photolytic destruction in high UV environments. Third is the case where our (Earth-based) technology is insufficiently sensitive. For example, the microbial biosignature, nitrous oxide (N₂O) while strongly attributable to life, has rather weak spectral absorption features, which could be overlooked (related to this point, see also the entry on the retrieval of atmospheric properties of exoplanets).

False Positive

John Lee Grenfell
 Institut für Planetenforschung, Extrasolare
 Planeten und Atmosphären, Deutsches Zentrum
 für Luft- und Raumfahrt (DLR), Berlin, Germany

Definition

A “false positive” refers to evidence which seemingly supports a particular hypothesis or test but which in fact results from unrelated causes. In an astrobiological context, “false positive” refers to evidence which suggests the existence of life but which in reality arises due to abiotic processes which are merely mimicking life.

Overview

Scientific validation of a proposed biosignature requires the assessment and elimination of all known abiotic (nonlife) processes (known as the “false positives”) which could also produce such a signal. There are essentially two issues: first to elucidate whether the *species* associated with the signal (e.g., in the case of atmospheric constituents such as ozone, methane, and oxygen) is being produced by life or by abiotic processes (this point is discussed further in the ► [Biomarker](#) entry), and second, to investigate whether the *signal* itself (e.g., the atmospheric spectral band) is uniquely attributable to a biosignature gas, i.e., one can rule out or subtract the effects of (partially) overlapping spectral bands arising from other gas-phase species, as well as interference from other phenomena, e.g., the presence of clouds, pressure broadening, etc.

Keywords

Carboxylic acids · Cellular membranes ·
Lipids · Molecular fossils · Organic acids

Synonyms

[Aliphatic carboxylic acids](#); [Alkanoic acids](#)

Definition

Fatty acids are ► [carboxylic acids](#) with an aliphatic tail (chain) that may be branched, saturated, unsaturated (i.e., contain double bonds), or contain cyclic moieties. Fatty acids typically have C₁₂–C₃₆ chain lengths, though chains of only four carbons are considered “fatty.” Fatty acids are constituents in a variety of biomolecules and are released by the hydrolysis of the ester linkages. Fatty acids are important components of cellular ► [membranes](#) of ► [bacteria](#) and eukaryotes, regulating both fluidity and permeability, and are key energy stores. Fatty acids have also been observed in carbonaceous meteorites (Sephton 2005).

Overview

In sediments and rocks, fatty acids may exist as free fatty acids (i.e., hydrolyzed form) or bound into larger biomolecules or geomolecules (as in

macromolecular ► **kerogen**), or bound to minerals. Fatty acids have varying specificity for particular phylogenetic groups of bacteria and eukaryotes, and also for environmental conditions.

Most natural fatty acids have an even number of carbon atoms because they are biosynthesized by the multiple additions of C₂-acetyl units via the acetyl-CoA coenzyme. Organisms also biosynthesize a limited range of chain lengths and have varying degrees of unsaturation (particularly plants, algae, and bacteria). Biologically produced stereoisomeric configurations of unsaturated fatty acids are all *cis* (the Latin term *cis* describes the orientation of functional groups, on the same side, within a molecule; the opposite term is *trans*, meaning “on the other side” or “across”). All of these features are regarded as general biosignatures and are not observed in abiological fatty acids, such as those observed in meteorites or in synthetics.

Fatty acid abundance diminishes during early diagenesis primarily due to in situ microbial reworking (Meyers et al. 1995; Petsch et al. 2003, 2005). Preferential loss of unsaturated and short-chain moieties is commonly observed. However, in the presence of other refractory materials, fatty acids are incorporated into geomolecules that enhance preservation. Saturated, ω -hydroxyl, and α , ω -diacids are more resistant to diagenesis and have been observed in the ancient geological record. A variety of reactions can lead to the loss of carbon from the alkyl chain, which during later diagenesis leads to molecular patterns having a greater relative abundance of odd-carbon chain lengths. For example, decarboxylation of even-carbon chain length fatty acids leads to odd-carbon alkane chains. Further, thermal maturation and carbon loss of alkanes lead to a diminishing preference for odd or even chain lengths. Thus, in the rock record, molecular distributions of fatty acids and alkanes can indicate biological sources and a relative degree of diagenesis. In some cases, fatty acids from microbes living in rocks or petroleum reservoirs

can complicate molecular interpretations and are important records of recent processes.

Feeding Zone

Sean N. Raymond
Laboratoire d'Astrophysique de Bordeaux,
CNRS, Université de Bordeaux, Bordeaux,
France

Definition

A planet's feeding zone is the region within the ► [protoplanetary disk](#) from where solids can be gravitationally captured by the planet. The planetary feeding zone is schematically a ring in the protoplanetary disk, centered on the central star, the forming planet being located in the middle of the ring. The size of the feeding zone depends on different factors, in particular the planetary mass, its distance to the central star, and the dynamical state of the solids. Typically, the size of the feeding zone is of the order of a few times the Hill Radius of the planet.

The size and location of the feeding zone has an influence on both the formation process of the planet (and therefore the final mass of a planet) and its composition. Large feeding zones, which contain a lot of mass, are required for giant planet formation. Given that radial temperature gradients are thought to translate into compositional variations in the protoplanetary disk, a planet's feeding zone has consequences for its composition. A narrow feeding zone implies that the planet's composition should represent material condensed within a small range in temperatures, and a wide feeding zone implies significant radial mixing during accretion.

Fennoscandia

Pentti Hölttä¹ and Aleksandr Slabunov²

¹Geological Survey of Finland, Espoo, Finland

²Institute of Geology, Karelian Research Centre, RAS, Petrozavodsk, Russia

Synonyms

[Baltic shield](#); [Fennoscandian shield](#)

Definition

Fennoscandia is the geographic term that covers the Scandinavian countries, Finland, and the northwesternmost part of Russia. The geologic term Fennoscandian Shield (Baltic Shield in some literature) denotes the Precambrian units of this area. The Precambrian of Fennoscandia consists of Archean and Proterozoic rocks, this description dealing with the former.

Overview

Archean rocks comprise much of the eastern and northern parts of the Fennoscandian Shield. They have been divided into five major provinces: Karelia and Norrbotten in the west, Belomorian in the east, and Kola and Murmansk to the north (Slabunov et al. 2006).

Paleoarchean (3.60–3.20 Ga) TTG gneisses have been documented in a few localities in the Norrbotten Province and in the western and south-eastern part of the Karelia Province but in general Mesoarchean and Neoarchean (3.20–2.50 Ga) lithologies dominate, most rocks falling in a relatively restricted age range of 2.84–2.67 Ga (Hölttä et al. 2014, 2019). The Archean provinces comprised the central part of the Kenorland supercontinent that was formed at c. 2.70 Ga (Lubnina and Slabunov 2017). This supercontinent started to break up at the end of the Archean, marked by the intrusion of mafic magmas in the northern and eastern part of the Shield at around 2.5 Ga.

The oldest rock so far reported in the Shield is ca 3.5 Ga trondhjemitic gneiss exposed in the western part of the Finland (Mutanen and Huhma 2003). A tonalitic-trondhjemitic-granodioritic (TTG) association with subordinate ► [greenstone belts](#), paragneisses, granulite complexes, and migmatitic amphibolites dominates the Archean terranes. The TTG magmatism mainly occurred between 2.83 and 2.74 Ga and was followed by a brief period of sanukitoid magmatism between 2.73 and 2.70 Ga. Sanukitoids originate from melting of a metasomatized mantle source (Martin et al. 2010), probably as a result of a slab break-off following continental collision (Halla et al. 2009). The Archean crust was strongly reworked in collisional processes at around 2.71–2.64 Ga, resulting in high-grade metamorphism and partial melting, producing granulites, migmatites and abundant granitic-granodioritic-monzogranitic (GGM) intrusions. The youngest Archean igneous rocks are 2.67–2.61 Ga anorogenic alkaline granitoids that occur in the Keivy terrane in Kola, the 2.61 Ga Siilinjärvi carbonatite close to the western border of the Karelian Province, and 2.68–2.61 Ga mafic dykes in the northeastern part of the Shield (Slabunov et al. 2006).

The oldest (ca. 3.10–2.90 Ga) volcanic rocks are found in greenstone belts in the eastern and northwestern parts of the Karelia Province. Most greenstone complexes are 2.88–2.72 Ga old, often showing an association of plume-related komatiites and tholeiites, island arc-type calc-alkaline volcanic rocks, as well as ► [meta-sediments](#) and ► [banded iron formations](#) (Hölttä et al. 2014). The Sierik and Iringora greenstone belts in the Belomorian Province display ► [ophiolite-like](#) features (Shchipansky et al. 2004; Slabunov et al. 2019). Greenstone belts in the central parts of the Karelia Province are younger (2.75–2.73 Ga) and they have more island arc type lithological and geochemical characteristics than in the western and eastern parts of the Province. Mesoarchean and Nearchean 2.88 Ga and 2.72 Ga eclogites metamorphosed at 14–17 kbars are known in a few areas in the Belomorian Province (Volodichev et al. 2004; Mints and Dokukina 2020), although some recent age determinations

suggest that the eclogitization was a Paleoproterozoic process taking place at 1.9–1.8 Ga (Skublov et al. 2011; Liu et al. 2017).

Two types of microfossils were found in the Mesoarchean (3.00–2.87 Ga) greenstone belts of the eastern part of the Karelia Province: (1) Tubular microstructures, probably fragments of the sheaths of chemolithotrophic filamentous thermophilic microorganisms, being found in the siliceous sedimentary rocks in the basalt-komatiite association (Svetov and Medvedev 2012); (2) Microfossils represented by silicate coccoid forms and pyrite-marcasite spheroids and hollow tubes, being found in sedimentary rocks of an arc-type section (Vysotskiy et al. 2019). In the Belomorian Province, a Nearchean (2.80–2.78 Ga) greenstone belt contains carbonaceous shales, quartz arenites, and tuffaceous-sediments, which themselves hold problematic coccoid micro-organisms and filamentous microstructures (Astafieva and Rozanov 2009).

Fennoscandian Shield

► [Fennoscandia](#)

Ferment (Obsolete)

► [Enzyme](#)

Fermentation

Juli Peretó

Institut Cavanilles de Biodiversitat i Biologia Evolutiva, Universitat de València, València, Spain

Definition

Fermentation is an anaerobic ► [catabolism](#) of a reduced carbon source (e.g., glucose) to generate ► [ATP](#) within a strict internal ► [oxidation-reduction](#) balance. In many cases, the same substrate is used both as reductant and oxidant. The hallmark of fermentation is the accumulation of partially oxidized end products. Only a part of the chemical energy stored in the initial substrate is conserved during the synthesis of ATP, usually by a mechanism of substrate-level phosphorylation. Nevertheless, there are some examples of the involvement of an electrochemical ion gradient in the synthesis of ATP (e.g., citrate fermentation).

History

Antoine Laurent Lavoisier (1743–1794) collected the first quantitative data on alcoholic fermentation. Louis Pasteur (1822–1895) studied in depth the fermentation by intact living cells and defined this physiological process as “life without oxygen.” In 1897, Eduard Buchner (1860–1917) showed that fermentation could occur in cell-free extracts, inaugurating the genuine biochemical in vitro approach to living phenomena. Parallel studies on yeast alcoholic fermentation and anaerobic muscle glycolysis during the first half of the twentieth century contributed to the development of biochemistry as a science (Barnett 2003).

Overview

Many microorganisms, obligate or facultative anaerobic, are able to degrade extracellular polymers (e.g., polysaccharides, proteins, nucleic acids) and use the monomers (e.g., hexoses, pentoses, amino acids, purines, pyrimidines) as fermentable substrates. There are other substrates of fermentations such as organic acids (e.g., citrate, succinate, or malonate) or even aromatic hydrocarbons. In this latter case, fermentation appears as a metabolic task of several microbial species working together. Regarding amino acid fermentations, many anaerobic bacteria can catabolize single amino acids but grow better with amino acid mixtures (the Stickland reaction). In this case, some amino acids of the mixture act as reductants, whereas others are the oxidants.

The stoichiometric yield of ATP in a fermentation depends on the particular pathway used and can range from less than one up to 4 mol of ATP per mol of fermentable substrate. Microorganisms are capable of generating a wide array of end products during fermentation, including carbon dioxide, ethanol, lactate, butyrate, acetate, and propionate. In comparison to respiration (i.e., electron transport chain-dependent processes), fermentations are less energetically efficient because a lot of potential chemical energy is still retained in most of the end products. Thus, to compensate this relatively low-energy yield, large

amounts of fermentable substrate are used and most carbons from this can be recovered in the form of end products. Other anaerobic bacteria use the excreted end products of fermentations, building an anaerobic food chain with methanogens at the bottom. From a biotechnological point of view, however, since very ancient times, fermentations are widely used for the processing of food products, such as yogurt, cheese, beer, wine, or bread.

In a few cases, some ATP synthesis during fermentation is associated with the dissipation of an electrochemical potential gradient either of protons or sodium ions. These ion gradients can be generated by electron transport (e.g., fumarate reduction in *Propionibacterium*), membrane decarboxylases (e.g., sodium-pumping succinate decarboxylase of *Propionigenium modestum*), or electrogenic substrate translocation through membranes (e.g., lactic acid bacteria like *Lactococcus cremoris*).

When compared to the other energy-generating systems (such as respiration and photosynthesis), fermentation seems simpler at the structural and enzymatic levels. For this reason, in 1924, Oparin (1924) postulated that fermentation was the earliest metabolic mode.

Fermi Paradox

Nikos Prantzos
 Institut d'Astrophysique de Paris,
 Paris, France

Keywords

Extraterrestrial civilizations

Definition

The Fermi paradox, attributed to Italian physicist Enrico Fermi, concerns the apparent contradiction between the lack of any evidence for the presence of extraterrestrials on Earth and the view that extraterrestrial civilizations should be rather common in the Galaxy.

History

Fermi formulated his paradox in 1950, during a casual conversation in Los Alamos Laboratory with E. Teller and colleagues, with the famous phrase “where are they?” (or “where is everybody?”). His point was that, if there are many extraterrestrial civilizations, Earth should have been visited by one or more of them, long ago and many times over. The discussion went completely unnoticed for many years. The phrase “where are they?” attributed to Fermi but without comments is first encountered in a paper published in 1963 by American astronomer Carl Sagan. Sagan referred to this problem as “Fermi’s paradox” after American astronomer Michael Hart independently rediscovered Fermi’s arguments in 1975.

Overview

As all paradoxes, the Fermi paradox is better understood if its premises are explicitly stated:

1. There are many extraterrestrial civilizations in the Milky Way.
2. Our civilization is a typical one (not the first to have appeared, neither the most technologically advanced, nor the only one seeking to explore the cosmos and communicate with others).
3. Interstellar travel is not too difficult for civilizations slightly more advanced than ours.
4. Galactic colonization (either by some of those civilizations or their self-replicating robots) can be achieved in less than 10^8 years, i.e., less than 1% of the age of the Galaxy.

If hypotheses (a) to (d) are valid, the conclusion “they should be here” is logically deduced, and the Fermi paradox applies. It ceases to apply if one or more of its premises are refuted. Supporters of ETI (extraterrestrial intelligence) reject one (or more) of the assumptions (b) to (d), in order to save the key hypothesis (a). In contrast, opponents of ETI uphold the plausibility of (c) and (d), while rejecting (b) and even (a). For instance, British astronomer Fred Hoyle thought that interstellar distances make interstellar travel impossible. However, arguments most often discussed refer to the sociological rather than the physical aspects of the problem. Fermi believed that a technological civilization would be too short-lived, destroying itself before mastering interstellar travel. Long before him, the Russian savant and father of astronautics Konstantin Tsiolkovsky preferred the so-called “zoo hypothesis” (reformulated independently in 1973 by American astronomer John Ball), according to which advanced civilizations observe us from afar without interfering, for various reasons (e.g., waiting for us to gain “maturity” before joining the “cosmic club”).

All sociological arguments share a common weak point: It is hard to believe that any one of them applies to every single civilization in the Galaxy. Moreover, in such a case, assumption

(b) would be implicitly violated since we would be the only civilization seeking communication with others. The most “economic” solution to Fermi’s paradox consists in straightforwardly rejecting hypothesis (a): Technologically advanced civilizations are rare in the Galaxy (and, perhaps, we are alone).

History

Enrico Fermi (1901–1954) was an Italian physicist famous by his important contributions to the knowledge and development of the quantum world, mainly on the nuclear and particle physics. In 1926, Fermi discovered, independently of Paul Dirac, the statistical laws, nowadays known as the Fermi-Dirac statistics, governing the particle systems subject to Pauli’s exclusion principle (the fermions).

Between 1934 and 1936, he published two important papers on the artificial radioactivity produced by neutron bombardment and on the absorption and diffusion of slow neutrons (this one led to the discovery of nuclear fission). In

1938, he won the Nobel Prize in Physics for his work on those issues.

In 1939, Fermi and his family, his Jewish wife Laura Capon and their two children, Nella and Giulio, emigrated to the USA, where he worked in the Manhattan Project during World War II. In 1950, while working at the Los Alamos Laboratory, Fermi and some colleagues discussed about the possibility of existence of non-terrestrial intelligent life. Some of them supported the idea that due to the apparent size and age of the Universe, the probability of having been developed alien civilizations would be huge. And if so the aliens have had more than enough time to travel around the Galaxy and visit the Earth. This prompted Fermi to ask, where are they? This significant issue became known as the Fermi paradox. In the 1980s, there is a massive scientific production of writings by scientists in and out of the SETI community to address the Fermi paradox.

The NASA’s Fermi Gamma-ray Space Telescope was launched in 2008 with the scientific mission to study high-energy phenomena and the exotic gamma-ray sources, from ancient black holes, to rapidly rotating neutron stars, or pulsars, in the Milky Way galaxy, to jets powered by supermassive black holes in far-away young galaxies.

Fidelity

Carlos Briones
Centro de Astrobiología (CSIC/INTA), Consejo Superior de Investigaciones Científicas, Madrid, Spain

Synonyms

[Replication accuracy](#)

Definition

In molecular biology and genetics, fidelity is the accuracy of template-dependent nucleic acid copying, in particular DNA or RNA replication. Since accurate genome replication is critical for the viability of cellular organisms, proofreading mechanisms ensure near-perfect fidelity for DNA replication, with average error rates of 10^{-9} – 10^{-12} mutations per nucleotide and round of copy. In turn, the lack of proofreading activity in viral RNA polymerases and reverse transcriptases results in low-fidelity replication, with average error rates of 10^{-3} – 10^{-5} mutations per nucleotide and round of copy.

Fig Tree Group

Christoph Heubeck
Institut für Geowissenschaften, Friedrich-Schiller-Universität Jena, Jena, Germany

Keywords

Archean ocean · Barite · Chert · Banded-iron formation · Early life

Definition

The Fig Tree Group overlies the Onverwacht Group and is overlain by the Moodies Group in the Paleoarchean ► [Barberton Greenstone Belt](#), South Africa and Swaziland. Strata of this group were deposited between approximately 3258 ± 3 and 3225 ± 3 Ma, reach up to 3 km in thickness, and show a wide variety of depositional settings and lithologies.

Overview

The Fig Tree Group consists largely of interbedded siliciclastic and chemically precipitated sedimentary strata, deposited in a range of settings, as well as intermediate to felsic volcanics. In contrast, underlying strata of the ► [Onverwacht Group](#) are dominated by mafic and ultramafic volcanics, with very little terrigenous contribution; strata of the overlying ► [Moodies Group](#) consist largely of shallow-water quartz-rich sandstones. Hofmann (2005) and Lowe and Byerly (2007) provide reviews of the stratigraphy of the Fig Tree Group.

Aside from thick fan-delta conglomerates, turbiditic greywackes, and fine-grained ferruginous and tuffaceous strata (Heinrichs 1980), the Fig Tree Group south of the Inyoka Fault includes thick jaspilitic ► [banded-iron formation](#) (within the Ngwenya Formation of Hofmann 2005), multiple sedimentary barite beds (in the lower Mapepe Formation near the base of the Group), banded carbonaceous ► [cherts](#), and several – in part reworked – impact-derived spherule beds. Fig Tree strata north of the Inyoka Fault largely consist of deeper-water turbiditic siliciclastic rocks. Northern and southern facies are overlain by dacitic volcanic and volcanoclastic rocks of the Schoongezicht Formation (Condie et al. 1970) and the Auber Villiers Formation, respectively (Lowe and Byerly 1999).

Together, these lithologies provide a wealth of unique insights in the chemical and physical setting of the Archean ocean, demonstrating the interplay of organic matter, dissolved Fe, Si, and Ba, and the temporary presence of (photolytically generated?) sulfate (Knauth and Lowe 2003; Bao et al. 2007; Roerdink et al. 2013). The volcanic strata and hypabyssal intrusions in the Fig Tree Group are contemporaneous with TTG plutons adjacent to the BGB, adding another tectonic perspective to our understanding of this unit.

The Fig Tree Group developed in a highly structured paleotopography, including terrestrial alluvial fan deltas, above-wavebase platforms, shelf bank settings, and various deepwater facies. The reasons for the complex paleotopography

may relate to the setting at the margin of the Onverwacht volcanic plateau, syndepositional deformation related to major thrusting (early D2 of Lowe and Byerly, 2007), and the proximity to the Inyoka Fault system. Lowe (2013) suggested that major meteorite impacts (recorded by spherule beds) may have contributed to the change in tectonic setting. Subsequent deformation, however, has overprinted many of the original depositional relationships. Lithology, provenance, depositional environment, volcanism, and style of deformation of the Fig Tree Group are compatible with a tectonic setting analogous to a modern convergent margin, such as a retroarc foreland, interarc, or forearc basin. In that regard, the Fig Tree strata record a transition from the oceanic-plateau setting of the underlying Onverwacht Group to shallow-water continental settings of the overlying Moodies Group.

Fischer Projection

Henderson James Cleaves II
 Earth-Life Science Institute (ELSI), Tokyo
 Institute of Technology, Tokyo, Japan
 Blue Marble Space Institute of Science,
 Washington, DC, USA
 Center for Chemical Evolution, Georgia Institute
 of Technology, Atlanta, GA, USA

Definition

In chemistry, a Fischer projection is a two-dimensional representation of a three-dimensional organic molecule devised by Emil Fischer in 1891. Fischer projections depict the stereochemistry of molecules and are thus useful for depicting enantiomers of chiral molecules, especially monosaccharides. The carbon backbone of the molecule is depicted as a vertical line and the bonds of side chains are represented as horizontal lines, with carbon atoms represented by the center of crossing lines. The orientation of the carbon chain is such that the C¹ carbon is at the top of the

molecule diagrammed. Vertical lines lie either in or behind the plane of the paper, while horizontal lines project out from the surface. In a Fischer projection, the plane of symmetry (3D) between two enantiomers becomes a line of symmetry between their 2D representations.

Definition

In Fischer-Tropsch-type (FTT) synthesis hydrocarbons are produced through hydrogenating carbon monoxide via surface-mediated reactions, as shown in reaction (1):

The FTT catalytic sequence, as other forms of catalysis, is rather complex and involves several

related reactions on the catalyst surface. A typical FTT experiment involves circulating gases (typically CO and H₂) through and/or over a catalyst at a specific temperature and then measuring the resulting gases (such as water, methane, and carbon dioxide) and residue on the grains as reaction time progresses. As the grains became coated with residue, organics are produced faster and in greater quantities and CO is quickly depleted. The reaction eventually reaches a plateau. Once this point is reached, the gases are removed and the system refilled to be run again.

History

Fischer-Tropsch-type synthesis is a common industrial process developed by coal researchers Franz Fischer (1877–1947) and Hans Tropsch (1889–1935) for obtaining gasoline and other liquid fuels from coal by indirect catalytic hydrogenation of carbon oxides (Hindermann et al. 1993). FTT chemistry was a natural extension of the pioneering work of Sabatier and Senderens (1902), who synthesized ► [methane](#) by passing a mixture of ► [hydrogen](#) and CO/CO₂ over a reduced nickel catalyst. It is important to remember that formation of methane (CH₄) alone is not the Fischer-Tropsch reaction but simply methanation. FTT synthesis was widely used in Germany during World War II to manufacture organic fuels in the form of gasoline, diesel oil, liquefiable gases, and paraffin wax. Early FTT experimentation used nickel and then iron catalysts. However, iron suffered from excessive carbon deposition leading to blockage of the ► [catalyst](#) pores and deactivation (Pearce et al. 1989). As a result, modern FTT plants typically use precious metals, cobalt, or nickel dispersed on substrates (alumina, silica, etc.). In actuality, many of these “fresh” catalytic surfaces are oxides, and it is these metal oxides that have industrial catalytic properties.

Overview

The origins of organics in the early Solar System are complex and still somewhat poorly

understood (Ehrenfreund and Charnley 2000). However, Fischer-Tropsch-type (FTT) catalytic reduction of CO by hydrogen to produce methane and other ► [hydrocarbons](#) has long been recognized as an important potential source of organic material in the ► [Solar Nebula](#), since the “basic ingredients” of this reaction (H_2 , CO, and plausible catalysts) were ubiquitous in this environment (Kress and Tielens 2001). Hayatsu and Anders (1981) compared the results of a wide range of experimental studies of FTT reactions to detailed analyses of the organic residue extracted from ► [carbonaceous chondrites](#). They reported that a significant fraction of the longer-chain hydrocarbons and more complex aromatic compounds in meteorites could be explained by FTT chemistry. However, there are some notable exceptions. In particular, ► [amino acids](#) are not produced efficiently enough or in the proportions and compositional distributions observed in meteorites via FTT reactions. This is in contrast to the Miller-Urey synthesis, which has been successful in generating many of the amino acids associated with living systems and carbonaceous chondrites.

In experimental studies of FTT reactions, pulverized iron-nickel meteorites, powdered carbonaceous chondritic meteorites, and synthetic substrate-supported nickel-iron particles have been used as the active catalyst (Hayatsu and Anders 1981; Llorca and Casanova 2000). In astrochemical experiments designed to measure the efficiency of FTT reactions (Hong and Fegley 1998; Fegley 1999), metallic iron (or iron oxide) was also used as the catalyst. These materials are relevant in that they were surely present in the primitive nebula. However, the bulk form of iron meteorites is not conducive to efficient catalysis, nor is there evidence that iron-nickel particles that might have been found in the nebula would have been analogous to powdered iron meteorites. In addition to the abovementioned materials, preliminary experiments (Ferrante et al. 2000) demonstrated that iron silicate grain analogues – even those containing 10% total iron – are effective FTT catalysts.

Amorphous iron silicates provide reasonably good surfaces to promote the reaction of H_2 , N_2 , and CO to organic materials, resembling those

found in meteorites (Hill and Nuth 2003; Gilmour et al. 2002). Although not as efficient, amorphous magnesium silicates, bronzite, and a range of other natural materials also promote the formation of organic materials from H_2 and CO. Fortunately, the amorphous metal-silicate grains or “smokes” are straightforward to produce in the laboratory and serve as good early Solar Nebula catalyst analogues. In addition to producing volatile organics via the reaction of H_2 and CO on these surfaces, a major reaction product appears to be a macromolecular organic coating on the grain surfaces. However, there is no significant decrease in the reaction rate of volatiles even when this coating comprises up to 10% by mass of the starting material (Gilmour et al. 2002). This implies that the organic coating formed as one of the initial products on any grain surface may also act as an additional effective catalytic surface for the conversion of H_2 , N_2 , and CO into organic materials. These coatings are composed of macromolecular organic phases (Johnson et al. 2004, 2007). These experiments also showed that as the grains became coated, Haber-Bosch-type reactions (catalytic reduction of N_2 by hydrogen to make ammonia) took place, resulting in nitrogen-bearing organics (Hill and Nuth 2003).

These types of FTT reactions are an effective means to produce complex hydrocarbons. Organics generated by this technique could represent the carbonaceous material incorporated in comets and meteorites.

Key Research Findings

Dust grains falling into a protostellar system can provide surfaces that promote the reaction of H_2 , N_2 , and CO into both volatile organics and a macromolecular coating that continues to promote the formation of organic materials. Although the reaction is most efficient in the innermost regions of the nebula, this does not pose significant problems as the reaction products as well as the coated grains can migrate back out to the far reaches of the nebula, thus seeding the entire nebula with the organic building blocks of life (Nuth et al. 2008).

Acronyms

FTT

Definition

The Fischer-Tropsch-Type (FTT) reaction is an industrial process to synthesize hydrocarbons and some aliphatic compounds in the presence of a metal catalyst. The carbon isotope ratios of produced hydrocarbons (methane and short-chain hydrocarbons) and by-products, such as carbon dioxide, show large fractionations relative to the reactants. Abiotic organic products are depleted in ¹³C to a degree like that caused by biological

processes. In specific geological environments, FTT reactions take place sourcing abiotic carbon in rocks and mimicking biosignatures.

History

Franz Fischer and Hans Tropsch developed the original Fischer-Tropsch process at the *Kaiser-Wilhelm-Institut für Kohlenforschung in Mülheim an der Ruhr*, Germany, in 1925. The German firm Brabag (Braunkohle Benzin AG) then commercialized it in 1936. Being petroleum-poor but coal-rich, Germany used the Fischer-Tropsch process during World War II to produce *ersatz* (replacement) fuels.

Overview

Fischer-Tropsch-Type reactions can produce various light and heavy hydrocarbons, oxygen-containing compounds (alcohols, carboxylic acids), and basic N-compounds, including amino acids (Hayatsu and Anders 1981). It is now widely accepted that at temperatures and pressures typical of the continental crust and the mantle, and in presence of natural metal catalysts such as iron, FTT can produce carbonaceous matter. Astrobiologists are particularly interested in FTT reactions in the seafloor hydrothermal environments, since these are the environments where Hadean or Archean life could have originated. It is believed that graphite from sedimentary rocks could have sourced non-biological carbon formed from FTT synthesis during seafloor serpentinization.

The carbon isotopic compositions of the carbonaceous products of FTT reactions display various extents of isotopic fractionation relative to the reactants. The majority of products are depleted in ^{13}C , with $\delta^{13}\text{C}$ values (where $\delta^{13}\text{C} = [(^{13}\text{C}/^{12}\text{C})_{\text{sample}} / (^{13}\text{C}/^{12}\text{C})_{\text{standard}} - 1]$, with the standard being the Pee Dee Belemnite) ranging from 2‰ to 60‰ (‰ = permil) depletion compared to the reactants. Several investigators (e.g., Kerridge et al. 1989; Lancet and Anders 1970) synthesized hydrocarbons from CO and

H_2 at 100–500 °C in the presence of metal catalysts (Fe, Co, Ni, magnetite, etc.) and proposed that such a process could explain the origin of carbonaceous and graphitic matter in meteorites. Their results indicated that short-chain hydrocarbons ($\text{C}_1\text{--C}_4$) were usually more depleted in ^{13}C than the reactant CO. However, the carbon isotopic signature of experimentally produced methane (CH_4) can vary significantly, from very depleted values of –60‰ to values even heavier than the reactant CO (Lancet and Anders 1970).

Horita and Berndt (1999) conducted a series of experiments to investigate isotopic fractionation during hydrothermal production of CH_4 from CO_2 and H_2 in the presence of Ni-Fe alloys. These experiments simulated the production of abiotic methane and other organic compounds during serpentinization. The $\delta^{13}\text{C}$ values of abiotic CH_4 produced from dissolved CO_2 with a mantle-like ^{13}C signature varied from –4‰ to –50‰, overlapping typical $\delta^{13}\text{C}$ values of microbial CH_4 . McCollom and Seewald (2006) produced H_2 , CO_2 , CH_4 , and light hydrocarbons ($\text{C}_2\text{--C}_5$) by heating an aqueous solution of formic acid (HCOOH) in the presence of iron powder at 250 °C and 325 bars in a hydrothermal cell. The $\delta^{13}\text{C}$ of the dissolved CO_2 was –14‰, and values for methane and light hydrocarbons were as low as –49‰. Again, these results show that organic products are depleted in ^{13}C to a degree typically ascribed to biological processes, indicating that the carbon isotopic composition may not be an effective diagnostic means to differentiate between biologic and non-biologic sources (McCollom and Seewald 2006).

Fitness

Susanna Manrubia

Systems Biology Program, Centro Nacional de Biotecnología (CSIC), Madrid, Spain

Keywords

Environment · Natural selection · Phenotype · Reproduction · Survival

Definition

Fitness is a central concept in evolutionary biology. It usually refers to the average capacity of an organism (as described by its ► [genotype](#)) to produce viable progeny. The genotypes of fitter organisms become more abundant through the action of ► [natural selection](#) along subsequent generations. Fitness is, however, a relative concept since the same genotype, which is the unique heritable material, might express different ► [phenotypes](#) in different environments. In turn, the ability of a phenotype (upon which natural selection acts) to reproduce successfully depends on the ► [environment](#). The quantification of the relationship between genotype and fitness remains an open problem.

Overview

Fitness is commonly defined as the ability of an organism to pass its genes to the next generation. However, many different organismal and environmental traits are involved in the successful completion of this process, and the mathematical form of fitness is therefore difficult to cast. Often, the fitness of a single trait is instead addressed, that is, the advantages conferred by that trait to the individuals carrying it. Actually, the first quantification of fitness measured the relative advantage of an organism with a mutant trait (or genotype) with respect to the non-mutated original type (Haldane 1924). Still, the fitness value of a trait does not depend only on how it performs in comparison to other genotypes, as the case of the mutant allele causing sickle-cell anemia illustrates. In a normal environment, homozygous individuals may experience severe blood disorders. However, the disease confers certain resistance to malaria, enough for heterozygous individuals to be at an advantage in environments where malaria is common, thus enhancing the prevalence of sickle-cell anemia in those regions.

The definition of fitness as the number of offspring of an organism has been challenged since the beginning of evolutionary theory. Already Fisher discussed the case of two individuals having the same number of offspring, the first one breeding only female offspring and the second one breeding half female and half male offspring. Though they are equally fit in terms of the definition above, the progeny of one of them cannot reproduce, and thus that lineage would go extinct if left on its own (Fisher 1930). Hamilton extended the idea of fitness as number of offspring (or number of genes that are passed to the next generation) to include the number of genes an individual can contribute to the next generation by helping kin relatives to reproduce. This is called inclusive fitness (Hamilton 1964).

Several issues have prevented the reaching of a consensus definition for fitness. They include whether fitness is better represented as a short-term or as a long-term quantity; the role played by chance and causality in the fate of populations; whether it should be applied to

species, organisms, or genotypes; and how to consider its dependence on the environment where organisms reproduce and compete with each other (Byerly and Michod 1991; Abrams 2009). As a result, fitness is used with different meanings in different situations, some of them being individual fitness, absolute fitness, and relative fitness (Orr 2009).

Synonyms

[Plug-flow reactor](#)

Definition

A flow reactor is a temperature- and pressure-controlled reaction vessel with opposite inlet and outlet ends for isothermal exposure of aqueous or gaseous samples under laminar flow conditions. These systems consist of a narrow-bore reactor with an in-line pump and back-pressure regulator and provide an alternative to batch-type reactors. Residence time is equivalent to the ratio of total reactor volume to the volumetric flow rate ($t_r = \frac{V}{v}$), and variable exposures are achieved by adjusting flow rate within the laminar flow regime. Flow reactors are commonly used to investigate aqueous chemical reactivity in high-temperature, high-pressure systems and are commonly utilized in astrobiology for investigation into prebiotic organic synthetic pathways that might be possible at submarine hydrothermal systems (SHSs). High-temperature systems ($\geq 100^\circ\text{C}$) include a rapid cooling stage before ambient sample collection (Fig. 1) to minimize

hysteresis effects. Materials for high-temperature flow reactors include corrosion-resistant metals such as high-nickel steel alloys or gold-plated surfaces.

Institut de Physique du Globe de Paris (IPGP),
Paris, France

Keywords

Fluid chemical composition · Fluid-rock interaction · Pressure · Homogenization temperature

Synonyms

[Fluid-bearing micro cavities](#); [Trapped fluids](#)

Definition

A fluid inclusion is a fluid phase present in the rock porosity or filling fractures that is trapped in microscopic cavities during mineral growth or fracture healing. Inclusion fluids can be of sedimentary, metamorphic, or magmatic origin. They can be thought of as time capsules storing information about ancient temperatures, pressures, and fluid compositions relevant at the time of trapping. The composition of most fluids falls in the C-O-H-S-N (H_2O , CO_2 , CH_4 , H_2S , N_2) + NaCl system, with NaCl representing the salt content of the fluid (expressed in weight% NaCl equivalent).

Overview

When crystals grow or recrystallize in a fluid medium of any kind, growth irregularities of many sorts trap microscopic portions of the ambient fluid in the solid crystal. These irregularities are called fluid inclusions. The sealing off of such irregularities may occur during the growth of the surrounding crystal, yielding primary fluid inclusions, or by recrystallization along fractures at some later time, yielding secondary inclusions. Fluid inclusions lining mineral growth zones are the best criteria for a primary origin. Secondary inclusions occur generally along planes cutting across several mineral grains. Fluid inclusions in rock samples are seldom of a unique origin. The presence of fluid inclusions in a rock is the rule rather than the exception. Indeed, the rock sample that contains no inclusions that are visible at high magnification ($>600\times$) is rare, and many minerals such as milky quartz may contain up to 10^9 fluid inclusions per cubic centimeter.

Fluid inclusions are present in all types of rocks, being sedimentary, metamorphic, or igneous in origin. They have been traced down to mantle depths and were found in ultrahigh-pressure minerals such as diamond. They occur in rocks as old as 4000 Ma and have been identified in lunar and meteoric samples. Because fluid inclusions are almost ubiquitous in geological samples, their study is applicable to a variety of geological problems and areas. Fluid inclusions have played a central role in oil and ore exploration research and in evaluating the safety of sites for both nuclear reactors and atomic waste repositories. Gas inclusions in polar ice sheets have permitted reconstruction of CO_2 concentrations of the recent atmosphere, fluid inclusions in speleothems (cave deposits) have provided data on paleotemperatures during the last 350,000 years, and inclusions in samples 3500 Ma old may provide geochemical constraints on the composition of the Earth's primitive atmosphere. In mantle and high-pressure rocks, fluid inclusions have helped clarify the nature and role of volatiles in a variety of geodynamic processes including element

recycling into the deep Earth, explosive volcanism at convergent margins, and the seismic behavior of the subducting plate. In metamorphic and sedimentary terranes, fluid inclusions have proven useful tools for containing the burial and exhumation history of crustal rocks and the pressure and temperature changes attending uplift and erosion of continental masses.

Fluid inclusions can be thought of as time capsules storing information about ancient temperatures, pressures, and fluid compositions relevant at the time of trapping. The basic assumption in all fluid inclusion studies is that the volume (density) and composition of the trapped fluid has not changed since formation of the inclusion or that, if an inclusion did leak, evidence for fluid loss is observable in the sample (decrepitation texture, microfracture, etc.). With the exception of magmatic rocks that can contain glass inclusions, that is, solidified melt inclusions, most rocks contain liquid and/or gas inclusions. At room temperature, a general distinction can be made between liquid and gaseous inclusions. Both types are often found in the same rock. This might indicate immiscibility between two phases at the time of trapping. Miscibility is a function of both the salt content of the aqueous phase and the gas composition. One or more solid phases can also be present. Solid phases can be either accidentally trapped particles that were present in suspension when the mineral grew or represent newly formed mineral that crystallized out of the fluids trapped in inclusions after sealing. In this case, the solid phase is called a daughter mineral.

Under the optical microscope, most fluid inclusions have a rather sharp outer boundary marking the edge of the inclusion cavity. This is because of a significant difference in refractive index between inclusion fluids and their mineral hosts: most aqueous fluids have refractive indices between 1.33 and 1.45, whereas the minerals in which they are included have refractive indices from 1.43 to as high as 3.22. Hydrocarbon liquids have refractive indices that may be similar to their mineral hosts and thus are not all easily visible. Given appropriate fluid inclusions, many aspects

of fluid composition can be determined. The composition of most fluids falls in the C-O-H-S (H_2O , CO_2 , CH_4 , H_2S) + NaCl system, with NaCl representing the salt content of the fluid (expressed in weight% NaCl content) and accounting for KCl, CaCl_2 , and other chlorides. Some fluid inclusions can also contain significant amounts of nitrogen (N_2). Bromine and fluorine can be important volatiles in some systems, but their abundances (as HBr and HF) are generally very low. In sedimentary rocks, oil inclusions can be present. The nature and concentrations of a large variety of major and trace elements can be obtained by crushing and leaching the inclusion fluids out of small samples containing a large number of inclusions or in situ, within a single inclusion. Information on the isotopic composition of light elements (H, C, N, O, S, and some noble gases) of the fluid can also be obtained.

If the composition of the inclusion can be determined and the liquid-vapor curve for that fluid is known, then the density can be determined from the temperature of homogenization of the vapor and liquid phases to one fluid phase. If the P-V-T properties of that fluid are known, then a line of constant density or molar volume is defined in a P-T space. This line, called an isochore, represents the range of P-T conditions over which a fluid of that density was trapped. If one can make an independent estimate of pressure or temperature at the time of trapping of the fluid in an inclusion, then both variables (P and T) can be uniquely determined using the isochore of the fluid. If both aqueous and gaseous inclusions are coexisting in the same healed fracture or fluid inclusion cluster, and the specific criteria for immiscibility between these two phases at the time of trapping can be ascertained precisely, then the intersection point between the two isochores in a P-T space corresponds to the temperature and pressure of trapping of the inclusion fluids.

History and Basic Methodology

The presence of fluids in rocks has been noticed since at least the eleventh century, but the first

fluid inclusion constituents (H₂O, CO₂, petroleum) were identified not before the eighteenth and nineteenth centuries (Dolomieu 1792; Sorby 1858). Sorby (1858) was the first to highlight a relation between metamorphism and filling of fluid inclusions. He suggested that the gas-liquid phases in fluid inclusions reflected thermally contracted fluids. He proposed that reheating inclusions would lead to disappearance of the bubble and that the temperature at which this occurred could serve as an estimate of the temperature of mineral formation. During the twentieth century, fluid inclusions were the subject of intense studies and debates by geologists from Russia, the USA, and Europe. The development and improvement of the equipment for quantitative analysis of fluid inclusions during the late 1960s and early 1970s paved the way to a vast number of geological applications using fluid inclusions as a petrological tool. Especially, a cooling-heating stage was developed (Poty et al. 1976), which expanded to low temperatures the temperature range for easily and accurately measuring phase transition in fluid inclusions. This technique known as “microthermometry” is indispensable for the analysis of single fluid inclusions and opened the possibility for the determination of fluid salinities and densities, and the consequent interpretation on the rock-forming conditions. Numerous analytical methods were developed since then for measuring fluid chemical and isotopic compositions. Among these, the introduction of laser Raman spectroscopy around 1980 (Dubessy et al. 1982; Pasteris et al. 1988) and synchrotron radiation micro-x-ray fluorescence (Frantz et al. 1988; Vanko et al. 1993; Philippot et al. 1998), Laser Ablation Inductively Coupled Plasma Mass Spectrometry (Heinrich et al. 2003), and Laser Microprobe Noble Gas Mass Spectrometry (Bohlke and Irwin 1992) around 1990 allowed quantitative analysis of anhydrous gas species (CO₂, N₂, CH₄, H₂S, and from then on H₂O), major and trace elements, as well as noble gases in individual fluid inclusions. Much of this work has been reviewed in the treatise on fluid inclusions published by Roedder (1984). Some of the important concepts and technical achievements

performed during this period are synthesized in Hollister and Crawford (1981) and Goldstein and Reynolds (1994).

Fluid Inclusions in Meteorites and Early Archean Sediments

The discovery of water-bearing fluid inclusions in 4.5 billion-year-old halite (NaCl) crystals preserved in the matrix of the Monahans and Zag H-► [chondrite](#) regolith ► [breccias](#) (Zolensky et al. 1999) provided important constraints on the fluid composition and P-T conditions in the near-surface environment of the ► [parent bodies](#). Minimum formation temperature of the inclusions has been estimated to be less than 100 °C and could have been as low as about 0.01 °C. The minimum pressure needed to stabilize a NaCl-saturated brine is 0.0754 MPa at 100 °C and 3×10^{-4} MPa at 0.01 °C. These conditions are consistent with the alteration having occurred in the shallow subsurface of the parent bodies. Moreover, the P-T conditions inferred for the formation of these inclusions is within the range of temperatures in which life has been observed to exist and thrive on Earth. Tiny fluid inclusions have also been found in two Martian meteorites (one in ► [Nakhla](#), NSNM 5891–3, and one in ► [ALH 84001](#), 146) (Bodnar 2000) and carbonaceous chondrites (Saylor et al. 2001). Although the fluid inclusions in the Nakhla sample occur as healed fracture and therefore are of secondary origin, the inclusions in the ALH 84001, 146 sample do not occur along fractures and therefore could be of primary origin, that is, trapped during growth of the enclosing pyroxene. The fluid in the inclusions may represent the magmatic fluid that exsolved from the crystallizing melt as the igneous rock formed on Mars. As such, the inclusions can provide valuable information about degassing early in Mars history. Optical behavior of these inclusions suggests that they contain liquid and vapor carbon dioxide.

Insights into the composition of the primitive terrestrial ocean and hydrothermal fluids (Cl/Br ratio, sulfur, and metal components) have been obtained by direct analysis of fluid inclusions preserved in poorly metamorphosed Archean sediments of the Kaapvaal Craton (South Africa) and

Pilbara Craton (Western Australia). Early studies performed in 3.2 Gyr-old (Channer et al. 1997; De Ronde et al. 1997) (but see Lowe and Byerly (2003) for a controversy on the origin of the samples considered) and paleoproterozoic 2.2 Gyr-old (Gutzmer et al. 2003) indicated that the Cl/Br ratio of the fluid trapped in the inclusions was below present-day seawater and resulted from mantle buffering, that is, hydrothermal in origin. However, these studies were based on bulk fluid analyses (i.e., crush-leach), which can result in fluid mixing if several fluid generations occur in a single sample. More recently, chemical analysis of individual fluid inclusions have been performed in 3.5 Gyr-old samples from the Pilbara Craton, Western Australia, by Synchrotron Radiation X-ray micro-Fluorescence (SR-XRF), thus allowing independent analysis of different fluids trapped in the same sample (Fiori et al. 2004). Individual fluid inclusion analysis using SR-XRF revealed the presence of three main fluid populations: a metal-depleted fluid, a Ba-rich and S-depleted fluid, and a Fe-S-rich end-member. The Cl/Br ratio of metal-depleted fluid inclusions (630) is similar to the modern seawater value (649) and was thought to represent a relic testimony of the primitive ocean. By contrast, Ba- and Fe-rich brines have Cl/Br ratios (350 and 390) close to bulk Earth value (420), hence arguing for a mantle buffering and a hydrothermal origin of these fluids. Model composition of “seawater component” has been evaluated to be 1100 mM Na, 2250 mM Cl, and 375 mM Ca, which corresponds to a bulk fluid salinity of 12 wt% salt equivalent. This high Cl concentration (ca. four times the present-day value) together with the occurrence of Cl/Br ratio similar to the modern seawater value (649) indicates that the Archean ocean formed on a typical modern-day seawater evaporation trend.

Fluorescent emission

Definition

When an electron in a substance is excited to a higher energy state by a photon, it may return to the lower energy state via a series of two or more intermediate energy states, assuming they exist. The photons which are re-emitted have a lower energy than the exciting photon and are consequently of a lower frequency and longer wavelength. This phenomenon is known as fluorescence. In some instances, two electrons may be adsorbed, allowing for emission of radiation of a shorter wavelength. As in UV spectroscopy, compounds often have unique fluorescence spectra which can be used in determining structure (see ► [Fluorometry](#)). Fluorescence detectors are extremely sensitive, thus this is an excellent analytical technique for trace amounts of substances. The infrared emission bands assigned to ► [polycyclic aromatic hydrocarbons](#) (PAHs) in a variety of astronomical environments have been attributed to fluorescence, with the exciting radiation being in the ultraviolet region of the spectrum.

Spectrofluorometry

Definition

Fluorometry is a chemical technique for measuring or monitoring ► [fluorescence](#). In fluorometry, the species is excited from its ground electronic state to an excited electronic state by absorption of a ► [photon](#) (typically from a UV source). The species returns to the ground electronic state by emitting one (resonance fluorescence) or more photons. The amount of fluorescence measured is used to determine the sample concentration by comparison with a standard or by using a calibration curve. Fluorometry is highly sensitive with up to femtomolar detection limits. In addition, fluorometry is considered a more specific technique than ► [absorption spectroscopy](#), since fluorescent molecules (fluorophores) are less common.

Keywords

Chromophore

Definition

A fluorophore is a molecule or a portion of a molecule that has fluorescent properties. While many compounds are inherently fluorescent as they contain fluorophores, there are many compounds that are not. For the sake of analyzing these latter types of molecules, a fluorophore is often introduced via chemical derivatization with a fluorescent reagent, for example, fluorescein isothiocyanate (FITC) or fluorescamine. Many widely used DNA stains and cell stains such as 4', 6-diamidino-2-phenylindole (DAPI) are fluorophore-containing molecules.

In the interstellar medium, infrared emission attributed to ► [polycyclic aromatic hydrocarbon](#) molecules (PAHs) is thought to result from fluorescence following the absorption of ultraviolet photons.

Flux, Radiative

Daniel Rouan
LESIA, Observatoire Paris-Site de Meudon,
Meudon, France

Definition

The radiative flux is the amount of electromagnetic power crossing one surface unit. In astronomy, it corresponds to the part of the power emitted by a celestial object received per area unit at the Earth. If the contributions at all the wavelengths are summed, one speaks of bolometric flux and the unit is W m^{-2} . If only a small interval in frequency (or wavelength) is considered, one speaks of spectral flux (unit: $\text{W m}^{-2} \text{Hz}^{-1}$). In the radio domain, the unit currently used is the Jansky ($10^{-26} \text{W m}^{-2} \text{Hz}^{-1}$).

Definition

Fomalhaut b is a massive planet orbiting roughly 115 AU (► [AU = astronomical units](#)) from the main sequence A-type star Fomalhaut, 25 light years from Earth. Paul Kalas, James Graham, and Mark Clampin discovered the planet in 2008 in a series of images of the star made by the ► [Hubble Space Telescope](#) (HST), showing the object to orbit the star just inside a narrow ring of dust. The planet's mass is constrained to the range

F

Fomalhaut b, Fig. 2 Northwest portions of the 2012 data (left) and 2010 data (right) with 5×5 median binning and a hard *grayscale* stretch to emphasize the northwest gap. The dotted lines are at P.A. = 329.8° and 332.8° in both

data sets. *Ovals* indicate background galaxies and Fomalhaut b is marked between *white line* segments. (Image from Kalas et al. 2013)

0.05–3 Jupiter masses based on the shape of the dust ring, which the planet stirs gravitationally. The ring of dust around Fomalhaut tipped off observers in the 1980s that this star might host a planetary system. Images of this narrow ring with the *HST* showed that the ring is not centered on the star; its center is offset from the star by 15 AU. This offset suggested the presence of a planet perturbing the ring, and led to the planet's discovery in 2008. The planet remains mysterious; it is several times brighter than expected for a body with this mass, and it has so far escaped observers who have tried to image it using other instruments. Fomalhaut b is considered the first extrasolar planet directly imaged by the *HST*; it is roughly a billion times fainter than the star it orbits (Figs. 1 and 2).

Methanal; Methyl aldehyde; Methylene oxide;
Paraformaldehyde

Definition

Formaldehyde (methanal, HCHO), the simplest ► **aldehyde**, is a one-carbon molecule intermediary along the redox continuum between CO₂ and CH₄, at the same oxidation state (0) as ► **graphite**. Formaldehyde was first reported by the Russian chemist Butlerow in 1860 and was conclusively identified by von Hofmann. It exists transiently but prominently in the abiological carbon cycle (Cleaves 2008). It is an abundant interstellar molecule and is a constituent of cometary ices (Biver et al. 2002, Schutte et al. 1993). It is readily produced in prebiotic simulation experiments from a variety of gas mixtures and energy sources.

HCHO may have played an important role in the synthesis of organic molecules relevant to the origin of life. HCHO is likely a significant precursor for the prebiotic synthesis of ► **glycine** and other amino acids (Miller 1957). HCHO can react to form sugars under basic conditions (Butlerow 1861) via the so-called ► **formose reaction**, a reaction of potential importance for the origin of an ► **“RNA World”** or early nucleic acids based on alternative sugars in a potential “pre-RNA

World” (Joyce et al. 1987). It has been argued that HCHO may in fact be the *only* one carbon C-, H-, and O-containing molecule capable of generating complex organic compounds for the origin of life (Weber 2002).

Overview

Basic Methodology

The geochemical behavior of formaldehyde is studied by a variety of techniques, including routine chemical analysis and laboratory simulation, spectroscopy, and various computational modeling approaches.

Key Research Findings

Prebiotic Sources of HCHO

One important source of HCHO on the primitive Earth is atmospheric photochemical synthesis by the photoreduction of CO₂ with H₂O:

Pinto et al. (1980) estimated that HCHO could be produced in yields of up to 10¹¹ moles/year, reaching a steady-state oceanic concentration of 10^{−3} M in 10⁷ years. Electric discharges acting on a variety of gas mixtures also produce HCHO in good yield (Stribling and Miller 1987); however, photochemistry may have been more significant simply due to the greater energy flux. Photochemical production from atmospheric CH₄ and/or CO could also have been a significant source of HCHO, though the production and rainout rates of HCHO are highly sensitive to energy source and atmospheric composition (Chang 1993).

HCHO could also potentially be produced in hydrothermal vents (Ferris 1994), for example, by the reduction of aqueous formate, CO or CO₂, or by the oxidation of methanol or CH₄, although HCHO does not appear to be a stable redox state of carbon under hydrothermal conditions. HCHO may be an intermediate in the redox equilibration of other more stable compounds (Seewald et al. 2006).

Prebiotic Sinks for HCHO

HCHO decomposes thermally in the gas phase above 300 °C to give CO and H₂ (Bone and Smith 1905) (Eq. 2):

Long-wavelength photochemical destruction was also likely a significant sink for HCHO (see below) (Calvert and Steacie 1951). Sekine (2002) found that MnO₂ catalyzes the oxidation of HCHO at room temperature to CO₂ under atmospheric conditions. Löb (1906) found that electric discharges acting on HCHO in the presence of water vapor give CO, CO₂, H₂, and CH₄ as products, which is essentially the reverse of the reaction demonstrated by Miller (1953).

There is reason to believe that there was a considerable flux of atmospherically synthesized and rained out H₂O₂ to the primitive oceans, particularly if the atmosphere was nonreducing (Kasting and Brown 1998). Reaction of HCHO with aqueous hydrogen peroxide gives formate and H₂ (Walker 1964) (Reaction 3):

Prebiotic Solution Chemistry of HCHO

An excellent monograph has been written on the chemistry of HCHO (Walker 1964). In an aqueous solution, HCHO is mostly present as the monohydrate, methylene glycol (Eq. 4):

HCHO absorbs UV radiation strongly in the range of 250–350 nm, resulting in photolysis. The hydrate does not absorb light at these wavelengths, thus dissolution in water could be an important photoprotection mechanism for HCHO.

Oligomerization Chemistry: Polyoxymethylene

Low-molecular weight polymers, ► **polyoxymethylene** (POMs) (of formula HO(CH₂O)_nH), form readily in neutral concentrated aqueous HCHO solution. The cyclic oligomers,

Formaldehyde, Fig. 1 Cyclic oligomers of HCHO, trioxane, and tetraoxane

trioxane, and tetraoxane (Fig. 1) may also form where acid catalysis is available.

Oligomerization Chemistry: The Formose Reaction HCHO can be oligomerized under basic conditions into sugars via the so-called formose reaction (Butlerow 1861) (see ► **Formose Reaction**). The equilibrium constant for the dimerization of HCHO to give ► **glycolaldehyde** is not well known, but is of considerable interest, since, while HCHO is volatile, glycolaldehyde is not and could thus be concentrated by evaporation.

HCHO reacts with ► **acetaldehyde** at much lower concentrations to give acrolein, among other products (Cleaves 2003).

The reaction of HCHO into formose is one limiting reaction pathway for the accumulation of HCHO in primitive waters, which would depend on the rate of HCHO production and delivery to the primitive oceans (Pinto et al. 1980). If HCHO became sufficiently concentrated, side reactions may have established the steady-state concentration regardless of the production rate. Given the observed photochemical synthesis of pentaerythritol (Fig. 2, left-hand side) (Schwartz and De Graaf 1993), and its likely mechanism of synthesis, it seems possible that HCHO is converted to CH₃CHO by UV light, and thus it appears unlikely that bulk oceanic concentrations of HCHO could have been much higher than 10^{−3} M.

HCHO is prone to photoreaction in the primitive oceans. For example, HCHO photochemically reacts to give mostly pentaerythritol

Formaldehyde, Fig. 2

2-Hydroxymethylglycerol and pentaerythritol: major products of photochemical reactions of HCHO

**Formaldehyde, Fig. 3** Hexamethylenetetramine (HMT) forms readily from NH_3 and HCHO

(Schwartz and De Graaf 1993), among other non-sugar products (Fig. 2) (Shigemasa et al. 1977).

Reactions with Amines

HCHO is converted to ► **hexamethylenetetramine** (HMT or 1, 3, 5, 7-tetraazatricyclo [3.3.1.1^{3,7}] decane) (Fig. 3) by reaction with ammonia (NH_3).

The reaction of fairly dilute ($\sim 0.003 \text{ M}$) aqueous HCHO and NH_3 between 100°C and 250°C produces amino acids, amines, and amino alcohols (Aubrey et al. 2009), and the reaction of somewhat more concentrated HCHO (0.02 M) with NH_3 (0.04 M) has been shown to produce traces of amino acids at lower temperatures (40°C) (Weber 1998). Thus, for at least several simple amino acids, NH_3 and HCHO may be sufficient for synthesis to occur.

Reactions with Sulfur Species

HCHO and H_2S react rapidly to produce trithiane and other oligomers (Fig. 4), which have been detected in hydrothermal vent effluent (Simoneit 1992), as well as in hydrothermal vent simulations (Cole et al. 1994) (Eqs. 5, 6, and 7):

**Formaldehyde, Fig. 4** Trithiane is formed from H_2S and HCHO

Aqueous HCHO reacts with SO_2 to give methylolsulfonic acid (Walker 1964) (Eq. 8):

The salts of this compound are nonvolatile, but decompose in dilute acid, liberating HCHO.

Mineral Interactions

There have been few studies of the adsorption of HCHO to minerals, though the ones that do exist suggest that HCHO clay adsorption equilibria are not especially high. This is generally also true for low molecular weight POMs (Parfitt and Greenland 1970). The adsorption equilibria may be more significant for clays such as illite and ► [kaolinite](#) (Chandra and De 1983). Clay adsorption may have led to significant concentration effects which may have facilitated reactions of HCHO such as oligomerization to formose products and redox reactions to ► [methanol](#), formate, and CO₂.

Reaction with HCN

Aqueous HCHO reacts readily with HCN to give glycolonitrile (Henry 1890) (Eq. 9):

The K_{eq} for the reaction is exceptionally high (Schlesinger and Miller 1973); thus, any atmospheric composition which results in the production of the two compounds essentially results in the production of ► [glycolic acid](#), after hydrolysis of the ► [nitrile](#).

Schwartz and Goverde (1982) found that the addition of HCHO or glycolonitrile to HCN actually accelerates the formation of HCN tetramer diaminomaleonitrile (DAMN). HCHO reacts readily with DAMN to form a crystallizable product (Koch et al. 2007).

Reaction of HCN, HCHO, and NH₃ produces the amino acid glycine via the Strecker synthesis.

Cannizzaro reactions may also be important loss channels for HCHO. If HCHO concentrations are high enough, HCHO disproportionates to form formate and methanol (Walker 1964), which reduces the concentration of HCHO available to form sugars. These reactions are acid-, base-, and metal- catalyzed (Walker 1964). As the reaction is apparently a third order, it is unclear whether it would occur significantly in dilute solution.

Interstellar Formaldehyde

Formaldehyde was the first polyatomic organic molecule detected in the interstellar medium by

Zuckerman et al. (1970). Since its initial detection, it has been observed in many regions of the galaxy. As the gas-phase reaction that produces formaldehyde is too inefficient to produce the abundance of formaldehyde that has been observed, it has been proposed that HCHO is formed via the hydrogenation of CO in ice (Eqs. 10 and 11):

There are several side reactions that take place with each step of the reaction that depends on the nature of the ice on the grain (Woon 2002). The isotopic ratio of [¹²C]/[¹³C] in HCHO in the galactic disk has been determined to be ~50:1 (Henkel et al. 1985), while the terrestrial ratio is ~100:1.

Formaldehyde in Biology

Free formaldehyde is rarely found in living metabolism, as formaldehyde is mutagenic due to its reactivity with proteins and nucleic acids. The main biological HCHO carrier is tetrahydrofolate; however, in methanogenesis, HCHO is masked as a methylene group in methanopterin.

Future Directions

A great deal remains to be discovered and quantified about the reactivity of formaldehyde in geochemical settings, and how this reactivity may have contributed to the complexification of organic materials for the origins of life.

Formamide (NH₂CHO)

Didier Despois

Laboratoire d'Astrophysique de Bordeaux,
CNRS-Université de Bordeaux, Bordeaux,
France

Synonyms

[Methanamide](#); [NH₂CHO](#)

Definition

Formamide (IUPAC name, methanamide) is the ► [amide](#) with the simplest structure (other amides have one, two, or three hydrogen atoms replaced by radicals). Formamide is the smallest molecule with a peptide bond. At room temperature and standard pressure, it is a colorless liquid. It remains liquid between 3 and 210 °C: this large range is one of the reasons for which formamide was proposed as an alternative to water as the “ideal” solvent for life. Above 90 °C, it decomposes to HCN and water. Ammonium formate, itself a product of the reaction of the two simple species, formic acid and ammonia, produces formamide when heated. Formamide is a potential starting material to create the RNA bases (Barks et al. 2010). Formamide has been found in the ► [interstellar medium](#) and in comets.

History

Formamide was detected for the first time in 1971 in the interstellar medium by Rubin et al. and in 1997 in the bright comet C/1995 O1 (Hale-Bopp) by Mehringer et al.

Sciences, University of Tuscia, Viterbo, Italy

Keywords

Formamide · Pyrimidines · Nucleobases
chemical synthesis

Synonyms

[N-\(pyrimidinyl\)formamide](#)

Definition

(1) Pyrimidine derivatives bearing one or more formylated amino moieties. (2) Formamide derivatives bearing one or two pyrimidinyl substituents on the amino group.

History

Formamido pyrimidines are key intermediates in the synthesis of purine and pyrimidine

nucleobases and analogues. They are produced during single electrophoretic line DNA sequencing procedures (Negri et al. 1991) by nucleophilic addition of formamide to C-8 position of purine nucleosides (Saladino et al. 1996). This reaction is one of the main DNA repair pathways under radiation and oxidative stress (Ober et al. 2003), and it catalyzed by the presence of mineral oxides (Saladino et al. 2003). Under prolonged sequencing procedures, formamido pyrimidines are further degraded to *N*-ribosyl urea and urea (Saladino et al. 1997). Examples of the synthesis of formamido pyrimidines under prebiotic conditions and their conversion into nucleobases and nucleosides are reported, including thermal condensation of formamide in the presence of montmorillonites (Saladino et al. 2004), multi-component reaction between malononitrile, amidinium salts and formic acid and metals (Becker et al. 2018), and condensation between formic acid and preformed aminopyrimidines (Becker et al. 2016). These procedures are characterized by high regioselectivity, simple one-carbon containing compounds, such as formamide and HCN oligomers, playing the role of both reagent and reaction medium (Yodav et al. 2020).

Formation of Planetesimals: The Building Blocks of Planets

Anders Johansen

Lund University, Lund, Sweden

Keywords

Dust · Particle concentration · Pebbles · Planet formation · Planetesimals · Protoplanetary disks · Streaming instability · Turbulence

Definition

Planetesimals are traditionally defined as solid objects (rocky or icy or a combination of both) whose internal strength is dominated by self-gravity rather than material strength. This corresponds to bodies of approximately 100 m to 1 km in size (Benz 2000). However, this definition does not take into account the role of the body in the planet-building process. Planetesimals of km in size are vulnerable to erosion and fragmentation in collisions with other planetesimals at the speeds relevant in protoplanetary disks (Ida et al. 2008). One can instead define the *planetesimal formation stage* as the growth of bodies to sufficient sizes to be insensitive to disruption in collisions with equal-sized bodies. This stage of planet formation may extend to as large as 1000 km in size, depending on the strength of the gas turbulence which is responsible for inducing high planetesimal-planetesimal speeds.

Overview

Planet formation takes place in ► [protoplanetary disks](#) of gas and dust which surround young stars. The embedded dust and ice particles represent only approximately 1% of the mass of the protoplanetary disk, but their structure formation

through collisions and sticking is responsible for the growth of planetary bodies.

The formation of *planetesimals* is an important step in the growth of planetary systems. Planetesimals are the building blocks of the rocky terrestrial planets (Mercury, Venus, Earth, and Mars) as well as the cores of the gas giants (Jupiter and Saturn) and the ice giants (Uranus and Neptune). The ultimate outcome of the planetesimal formation stage is the production of planetesimals of sufficient sizes to obtain gravitational cross sections much larger than their physical cross sections, hence accelerating the growth toward fully fledged planets. The gravitational cross section can here refer to either the ability to accrete other planetesimals (Levison et al. 2010) or to accrete mm–cm-sized pebbles facilitated by the strong gas drag felt by such small particles (Lambrechts and Johansen 2012).

The lack of ► [gravitational focusing](#) in the planetesimal formation stage means that direct sticking is key to particle growth. However, dust particles encounter many barriers and bottlenecks in their growth toward planetesimals, as bouncing and fragmentation become increasingly likely with increased size (Zsom et al. 2010). Particles of sizes from mm to several m are nevertheless concentrated in the turbulent flow of the gas, and the overdensities can become high enough for the collective gravity to be dominant (Johansen et al. 2007). This leads to the formation of large planetesimals (100–1000 km radii) by gravitational collapse of particle filaments and clumps.

Basic Methodology

Planetesimal formation can be studied observationally, experimentally, or theoretically. Important constraints on the planetesimal formation process are obtained from studying the structure and dynamics of minor bodies in the solar system – asteroids, Kuiper belt objects, and comets – or from studying debris disks around other stars. In the latter, the observed dust is produced through collisions within an (unseen) planetesimal population. In the Solar System measurements of size distributions, spectral classes and binarity have

proven useful for developing planetesimal formation models.

The outcome of collisions between particles of different sizes can be measured in the laboratory. Particle aggregates are typically built from micrometer-sized silicate monomers. These aggregates can then collide with each other and the outcome is measured in terms of sticking, bouncing, or fragmentation (Güttler et al. 2010), depending on the collision speed.

Knowing the collision outcome for a wide range of input parameters, the growth of populations of dust particles can be modeled on a computer. The collision speed depends on the sizes of the colliding particles. For small particles, the Brownian motion dominates, while larger particles have increasing contributions from the turbulent gas, peaking at approximately 5–50 m/s for m-sized particles under typical turbulent conditions.

Hydrodynamical simulations are used to investigate the concentration of particles in the turbulent gas flow of the ► [protoplanetary disk](#). Particle concentration mechanisms can be divided into two categories. *Passive concentration* occurs as particles pile up in regions of high gas pressure. On small scales of the turbulent flow, these regions reside between swiftly rotating turbulent eddies (which are themselves low pressures). Small particles, under some conditions similar in sizes to those stuck at the bouncing barrier (Zsom et al. 2010), concentrate between the eddies (Cuzzi et al. 2001). On large scales where Coriolis forces from the rotating disks are dominant, large-scale vortices and axisymmetric pressure bumps arise spontaneously in the turbulent flow (Johansen et al. 2009) or near transitions in the turbulent viscosity (Lyra et al. 2008). These geostrophic high-pressure structures concentrate large particles, of typical sizes from 10 cm to 1 m.

Active concentration occurs through the streaming instability (Youdin and Goodman 2005). This hydrodynamical instability arises in the coupled motion of particles and gas, from the free energy present between the inward-flowing particles and the outward-flowing gas in the midplane. The gas in the protoplanetary disk is slightly pressure supported in the radial direction,

since the gas is denser and hotter close to the star. The pressure support acts like a reduced gravity on the gas and causes the gas to orbit a bit more slowly than the Keplerian speed, by approximately 50 m/s. Solid particles do not sense the pressure gradient force from the gas and would orbit at the Keplerian speed in absence of friction, but the headwind of the slower moving gas drains angular momentum from the particles and causes them to drift toward the star. The drift speed peaks for typical particle sizes of 10 cm to 1 m, in the inner few AU of the protoplanetary disk, with a drift timescale as low as a few hundred years. Regions of slightly increased particle density drift more slowly toward the star as the gas there is accelerated toward the Keplerian speed by the drag force from the particles. The streaming instability causes an exponential increase of the density of the filament as isolated, fast-drifting particles continue to pile up in the overdense region.

Key Research Findings

Dust growth models have identified a number of bottlenecks in the planetesimal formation process. The *electrostatic barrier* describes the inability for dust grains to grow beyond a few 10 μm , as negatively charged aggregates repel each other (Okuzumi 2009). The *bouncing barrier* sets in at sizes from 0.1 to 1 mm, as compactified dust aggregates of these sizes will bounce rather than stick if collision speeds are higher than a few mm per second (Zsom et al. 2009). The *fragmentation barrier* sets in at collision speeds higher than 1 m/s, although growth can still be obtained if small impactors hit much larger targets at speeds up to 25 m/s (Wurm et al. 2005). Finally the formidable *radial drift barrier* requires that growth must be faster than the radial drift of particles (Weidenschilling 1977). Even if the radial drift barrier could be somehow overcome, the fragmentation barrier has second branch for km-scale planetesimals whose collision speed can be excited to super-escape values by the turbulent gas (Ida et al. 2008).

While ideas exist for circumventing the many growth barriers, e.g., by invoking sticky organics

(Kouchi et al. 2002) or dust rims to enhance sticking between the mm-sized chondrules which are found in meteorites (Ormel et al. 2008), any growth must compete with the radial drift of the particles. Global models of particle coagulation have only managed to produce planetesimals by sticking either in the innermost part of the disk (within 1 AU) or by assuming high sticking threshold speeds and invoking pressure bumps to stop the radial drift (Brauer et al. 2008).

Another path to planetesimal formation is through the concentration of particles in the turbulent gas flow, followed by a brief phase of gravitational contraction and collapse. Large-scale axisymmetric pressure bumps were identified already by Whipple (1972) as traps of drifting particles. Barge and Sommeria (1995) explored dust trapping in anticyclonic vortices – structures which could arise in protoplanetary disks around at transitions from weak to strong turbulence (Lyra et al. 2008) or at the edge of gaps produced by giant planets. Turbulence in protoplanetary disks may be driven by the magnetorotational instability (Balbus and Hawley 1991). Computer simulations of magnetorotational turbulence in accretion disks show the emergence of large-scale pressure bumps which trap dm–m-sized dust particles (Johansen et al. 2009). The streaming instability was discovered by linear stability analysis by Youdin and Goodman (2005). The process of piling up isolated particles into overdense filaments leads to very high particle densities, as high as 10,000 times the local gas density (Johansen et al. 2012).

The growth of particles by sticking and collapse of overdense particle filaments into planetesimals are not mutually exclusive. Particles must grow to sizes of at least mm in order to be able to concentrate in the turbulent gas, and some mechanisms like vortices and pressure bumps seem to require particles as large as 10 cm to begin with. Particle growth also does not stop at the collapse phase. Particle densities reach very high values during the contraction to solid densities and hence collision rates are high. The outcomes of these collisions determine the sizes of the planetesimals which emerge from the contracting clouds. Nesvorný et al. (2010) investigated the outcome of collapsing pebble clouds

and found that an initial mean rotation of the cloud (which could be inherited from the overall rotation of the disk) leads typically to the formation of a binary planetesimal surrounded by particles clumps which can be interpreted as a swarm of smaller planetesimals. This model agrees with the observation that the classical cold component of the Kuiper belt – the most pristine planetesimals in the Solar System which have undergone very little collisional and dynamical evolution – have a very high binary fraction.

Applications

Results from planetesimal formation models can be used as input for understanding the formation of planetary systems. The birth sizes of planetesimals can be applied to the asteroid belt to understand the origin of the current size distribution of asteroids as well as the emergence of the major asteroid classes. Water delivery to Earth is thought to have happened via collisions with icy planetesimals, so the origin of life on Earth is deeply connected to the formation of planetesimals.

Future Directions

An important priority for planetesimal formation studies in the future is to develop models of the growth of dust particles by sticking which take into account the concentration and gravitational collapse into planetesimals of a wide range of sizes. While many aspects of particle growth and concentration are well understood, the single most important parameter in determining which processes are dominant is the strength of the turbulence in the gas. Strong background turbulence suppresses the streaming instability so that particles must grow to sizes of at least 10 cm in order to concentrate in large-scale pressure bumps and vortices. The streaming instability can concentrate particles down to cm sizes if the turbulence is moderate or weak. Thus, an increased comprehension of the presence and strength of turbulence in protoplanetary disks will be crucial for understanding how planetesimals form in protoplanetary disks.

Formic Acid

Kensei Kobayashi
Yokohama National University, Yokohama, Japan

Synonyms

[Methanoic acid](#)

Definition

Formic acid is a carboxylic acid, whose chemical formula is HCOOH (Fig. 1). It has a dissociation constant in water ($\text{p}K_{\text{a}}$) of 3.74. It dissolves readily in water and is slightly soluble in hydrocarbons. It is mostly present as dimers in hydrocarbon solvents and in the gas phase. It can react as a reducing agent. It dissociates to carbon monoxide and water upon heating or by the addition of sulfuric acid. In an early report on the abiotic

Formic Acid,

Butlerow reaction

Definition

The formose reaction, discovered by Butlerow in 1861, is a complex autocatalytic set of condensation reactions of formaldehyde to yield sugars and other small sugar-like molecules. The reaction is particularly noteworthy in the context of astrobiology and prebiotic chemistry in that it could serve as a potential abiotic source of carbohydrates, in particular ribose, which could be important for the origin of an RNA World.

Overview

The formose reaction is an autocatalytic reaction discovered by Butlerow (1861). It involves the formation of sugars, polyols, and hydroxy acids from ► [formaldehyde](#) in a series of carbon-to-carbon condensations, as opposed to carbon-to-oxygen condensations of HCHO to form ► [polyoxymethylene](#). Formose is a contraction of formaldehyde and the suffix -ose, denoting a sugar. In fact, many biological sugars have empirical formulas of the form $(\text{CH}_2\text{O})_n$, for example, glucose, $(\text{CH}_2\text{O})_6$, and ► [ribose](#), $(\text{CH}_2\text{O})_5$. The formose reaction may be a mechanism for the prebiotic synthesis of sugars from formaldehyde, of relevance to the origin of an ► [RNA World](#) (Gesteland and Atkins 1993), early nucleic acids based on alternative sugars in a potential “pre-RNA World” (Joyce et al. 1987), as well as other sugar-based models for the origin of life (Weber 1997, 2001). The formose reaction is one of the few chemical systems proposed to be close to an autocatalytic proto-metabolic cycle (Orgel 2000).

Both formaldehyde and ► [glycolaldehyde](#) have been observed spectroscopically in outer space in both the ► [interstellar medium](#) and in comets (Hollis et al. 2000). Formaldehyde and sugar-related compounds, such as ► [glycerol](#), which could be derived from this reaction, are abundant in some carbonaceous chondrites (Cooper et al. 2001); thus, the formose reaction

could be a cosmically common abiotic mechanism for sugar synthesis.

Basic Methodology

The formose reaction has been studied as a chemical reaction traditionally, and thus approached using various analytical chemistry techniques. It has also been studied in various computational simulations.

Key Research Findings

Reaction Mechanism

The mechanism of the reaction has been studied intensively, and the complexity of the product mixture is notorious (Breslow 1959). The reaction is typically carried out from concentrated HCHO under alkaline conditions in the presence of divalent metal ions, such as calcium, magnesium, or lead, and is preceded by an induction period which can be shortened by the addition of glycolaldehyde or other aldehydes as initiators. Reaction does not proceed at an appreciable rate under neutral conditions at room temperature. At high pH, it is sluggish in the absence of catalysts such as divalent metal ions (Orgel 2000). It has been difficult to decipher whether the reaction *requires* divalent cations or higher aldehydes to initiate. It has been reported that carbohydrates and other trace impurities in commercial formaldehyde solutions or paraformaldehyde present in ppm quantities may be the cause of the autocatalysis observed in some of the formose reactions studied to date (Socha et al. 1980). For example, paraformaldehyde sublimed into $\text{Ca}(\text{OH})_2$ suspension was not transformed to sugars via the formose reaction, but only to methanol and formate by the base-catalyzed Cannizzaro reaction, and a 3 ppm trace of glycolaldehyde was sufficient to initiate conventional autocatalysis (Socha et al. 1980). However, at neutral or slightly basic conditions, redistilled formaldehyde solutions undergo the classical reaction (at 80°) in the presence of several minerals, while no reaction is observed in their absence (Schwartz and de Graaf 1993a; see below).

The reaction involves a series of intermediate steps including aldol reactions, reverse aldol reactions, and isomerization reactions. A number of intermediates have been identified including glycolaldehyde, glyceraldehyde, dihydroxyacetone, and tetroses. Figure 1 shows a simplified proposed mechanism for the reaction (Breslow 1959).

The reaction is proposed to begin with the apparently kinetically slow reaction of two formaldehyde molecules to make glycolaldehyde. Glycolaldehyde then reacts via an aldol condensation with another formaldehyde molecule to yield DL-glyceraldehyde. Isomerization of glyceraldehyde forms dihydroxyacetone (DHA), which can react with glycolaldehyde to form a 2-ketopentose. This 2-ketopentose may then isomerize to yield various isomeric pentoses. DHA can also react with formaldehyde to produce a 2-ketotetrose which can isomerize to give an aldotetrose. At this

step, the aldotetrose can react via a retro-aldol reaction to give two molecules of glycolaldehyde. Due to the generation of two molecules of glycolaldehyde from the input of one, the reaction becomes autocatalytic.

Mineral Interactions

Mineral adsorption may have been an important sink or concentration mechanism for HCHO and sugars. Mineral surfaces and other inorganic species can also have significant effects on the course of the reaction, as both general and selective catalysts for synthesis and degradation for the reaction products. There have been relatively few studies of the adsorption of HCHO to minerals, though the ones that do exist suggest that HCHO-clay adsorption equilibria are not especially high, which is also true for low molecular weight POMs (Parfitt and Greenland 1970). Adsorption equilibria may be higher for clays such as illite and kaolinite (Chandra and De 1983).

Formose Reaction, Fig. 1 A simplified scheme for the formose reaction. The stereochemistry of the asymmetric carbon atoms (marked with an *asterisk* in the diagram) is

not specified, but in general all isomers are formed. Side reactions leading to branched-chain molecules complicate the cycle and divert molecules from it

Many minerals appear to catalyze the formose reaction, for example, various clays, apatite, and calcite were found to be catalysts (Gabel and Ponnampertuma 1967; Reid and Orgel 1967; Cairns-Smith et al. 1972; Schwartz and de Graaf 1993b). The reaction can be carried out at lower pH and in the absence of glycolaldehyde initiator in the presence of some minerals (Schwartz and de Graaf 1993a). Certain mineral types, in particular ► borates and silicates, stabilize intermediates in the reaction pathway at high pH and might significantly alter the product mixture under these conditions (Ricardo et al. 2004; Lambert et al. 2010). This may be particularly significant given the wide distribution of silicates in the solar system. Double-layer hydroxide minerals have been shown to be catalysts for aldol condensations under very dilute conditions (Arrhenius et al. 1994).

Mineral effects have generally been studied using high concentrations of HCHO (0.01 M or higher) or other aldehydes; it remains unknown whether minerals affect the reaction of more diluted HCHO (see below).

Competing Chemistry

Cannizzaro Reactions

At high concentrations, HCHO undergoes a disproportionation reaction to form formate and methanol (Eq. 1) (Walker 1964), which reduces the amount of HCHO available to form sugars. These reactions are acid, base, and metal catalyzed (Walker 1964). The reaction reportedly shows third-order kinetics. It is not clear whether it would occur significantly in dilute solution.

Oligomerization to Polyoxymethylene

A series of low-molecular weight polymers, polyoxymethylenes (POMs) (of formula $\text{HO}(\text{CH}_2\text{O})_n\text{H}$) as well as small six- and eight-membered cyclic oligomers, form readily in neutral concentrated aqueous HCHO solutions. This polymerization is highly concentration dependant. A 5 wt% (~1.3 M) aqueous HCHO solution contains only ~14% POM dimer, 3% trimer, and

0.5% tetramer. Polymerization equilibria would be much lower for the prebiotic oceanic concentrations of HCHO which have been estimated.

Sugar Degradation

Under the basic reaction conditions which allow the formose reaction to occur, sugar decomposition into tars (Reid and Orgel 1967; Shapiro 1988), furans, and other low molecular weight degradation products (De Bruijn et al. 1986; Cooper et al. 2001) is also facilitated (Larralde et al. 1995). This has been shown to be less significant depending on the presence of high concentrations of inorganic species which may act as stabilizers (Ricardo et al. 2004; Lambert et al. 2010).

Photocatalysis and Reaction with CH_3CHO

The photochemical synthesis of formaldehyde from ultraviolet irradiation of CO_2 and water is quite robust (Pinto et al. 1980). Although its hydrate has a low-UV cross section, HCHO may have been prone to photoreaction in primitive surface waters. Schwartz and De Graaf found that UV irradiation of dilute solutions of formaldehyde-produced acetaldehyde (CH_3CHO) in significant yield, as well as very high yields of pentaerythritol (Fig. 2) (Schwartz and de Graaf 1993a). Other nonsugar products have been observed from photochemical formose reactions by others (Shigemasa et al. 1977).

Significant quantities of acrolein ($\text{CH}_2 = \text{CHCHO}$) have also been detected in spark discharge experiments (van Trump and Miller 1972). The ΔG for the condensation of CH_3CHO and HCHO in the gas phase was estimated at $-4.44 \text{ kcal mol}^{-1}$ and the K_{eq} as 1640 (Malinowski et al. 1963). Thus, the overall reaction is thermodynamically favorable.

Acrolein is an intermediate in the industrial synthesis of pentaerythritol from concentrated HCHO and CH_3CHO in aqueous alkaline solution (Berlow et al. 1958). HCHO reacts with CH_3CHO at much lower concentrations, to give acrolein among other products, than the formose reaction has been observed to occur (Cleaves 2003). The synthesis of acrolein from equimolar HCHO and CH_3CHO was found to be fairly independent of

Formose Reaction, Fig. 2 Scheme for the photochemical synthesis of CH_3CHO , acrolein, and pentaerythritol from UV irradiation of HCHO

pH between pH 7 and 11 and relatively independent of concentration between of 10^{-4} and 1 M. In contrast, glycolaldehyde and glyceraldehyde syntheses were found to be extremely concentration dependent. At 10^{-3} M concentration of equimolar HCHO and CH_3CHO and below, neither glycolaldehyde nor glyceraldehyde was detected. The same is presumably true of the higher sugars.

It has been demonstrated that acrolein is one of the few compounds with which the nucleobases of RNA/DNA will readily react (Nelsestuen 1980). Thus, acrolein could have been an important sink for the nucleobases in the prebiotic environment and a significant hindrance to the start of an RNA World.

Environmental Limitations

The efficiency of the formose reaction in a prebiotic environment is highly dependent on the rate of HCHO production and delivery to the primitive

oceans (Pinto et al. 1980). The reaction has been observed to occur with HCHO as dilute as 0.01 M (Reid and Orgel 1967; Schwartz and De Graaf 1993a), although there are accounts of its reaction as dilute as 10^{-3} M (Gabel and Ponnamperna 1967). These concentrations may have been difficult to achieve in the bulk early oceans. As HCHO became concentrated, side reactions may have established a low steady-state concentration regardless of the production rate. Given the observed photochemical synthesis of pentaerythritol described above, it may be unlikely that bulk oceanic concentrations of HCHO could have been much higher than $\sim 10^{-3}$ M.

If the concentration and reaction of HCHO on the primitive Earth were difficult because of all of the potential competing geochemical sinks, sugars may have been derived from meteoritic input. Polyols such as glycerol and ribitol have been identified in the Murchison meteorite, although the only actual sugar identified was DHA

(Cooper et al. 2001). This can potentially be explained by the instability of sugars over the ~4 billion years since the Murchison parent body formed and the observed organic synthesis presumably occurred. The initial synthesis to form sugars may have occurred relatively rapidly on the parent body, while only those compounds stable enough to survive until the present day are still detectable. The detection of these compounds does however present an interesting paradox for prebiotic chemistry. If the polyols and their precursors were generated by the same aqueous phase chemistry which produced the amino and hydroxy acids, as well as the purines and pyrimidines which have been detected in the Murchison meteorite (Pizzarello 2004), apparently the suggested inhibition of HCHO chemistry by HCN and vice versa (Schlesinger and Miller 1973) is not a genuine problem. The ratio of glycolic acid to glycine in Murchison suggests that NH_3 concentrations were fairly high in the parent body (Peltzer et al. 1984). These quantities also suggest that the reactions which form HMT and glycolonitrile are not limiting to either purine or sugar synthesis and that slow kinetic effects may be more important than the initial rapid equilibrium obtained.

The prebiotic oceanic concentrations of most precursor organic compounds such as HCHO and NH_3 were also likely quite low (Stribling and Miller 1987). It is necessary to consider the geochemical processes which might have concentrated HCHO sufficiently to allow the formose reaction to occur. It is worth considering what happens to dilute solutions of more complex mixtures of HCN, HCHO, and other aldehydes, NH_3 , urea, nitrate, nitrite, sulfides, ferrous iron, salts, etc., as they are evaporated in the presence of UV and visible light over mineral surfaces, or as they are frozen from dilute solution under visible and/or UV irradiation.

Possible Geological Settings for the Formose Reaction

Sugars are easily made by the reaction of HCHO under certain conditions (fairly high concentrations and slightly basic to basic pH). Such

conditions of pH and concentration are likely only attainable in certain geological environments such as in eutectics and in evaporative environments after HCHO is rendered nonvolatile by reaction with other aqueous species, for example, NH_3 , SO_3^- , or H_2S .

Eutectic Freezing

Eutectic freezing can effectively concentrate dilute prebiotic reactants to form purines, pyrimidines, and ► amino acids (Sanchez et al. 1966; Levy et al. 2000; Miyakawa et al. 2002). Whether HCHO can also be concentrated via eutectic freezing to form sugars is unknown, but plausible. One significant advantage of this process is that sugars are generally much more stable at low temperatures (Larralde et al. 1995). The eutectic freezing and thawing of precursor ice-grain organics such as HCHO in carbonaceous chondrites may have allowed for the synthesis of sugars on these bodies (Cooper et al. 2001). The frozen clay model proposed by Lahav and Chang (1976) may warrant careful reconsideration.

Concentration by Evaporation

Evaporative concentration is a plausible geochemical mechanism for concentrating nonvolatile species. The equilibrium constant for the dimerization of HCHO to give glycolaldehyde is not known, but is of considerable interest, since while HCHO is volatile, glycolaldehyde is not and could thus be concentrated by evaporation. A rough calculation using the free energy of the aldol reaction of HCHO given by Weber (2002) suggests the equilibrium constant is 40, but this does not take into account various kinetic factors which may limit the reaction. This simple reaction is worthy of further investigation from the standpoint of prebiotic chemistry, especially given the presence of glycolaldehyde in interstellar space (Hollis et al. 2000).

Hydrothermal Vents

Although some hydrothermal vent environments are characterized by rather alkaline conditions which would be ideal for formose chemistry, most modern vent systems are generally

characterized by low organic concentrations and moderate to very high temperatures and thus may not be optimal sites for formose chemistry. In addition to the thermal instability of sugars, HCHO does not appear to be a stable one-carbon species under hydrothermal conditions (Osada et al. 2004; Seewald et al. 2006).

Given the uncertainties regarding primitive Earth conditions, the existence of specialized conditions which would allow the formose reaction to occur cannot be ruled out. The synthesis of sugars in such environments from low initial HCHO concentrations under mild conditions might be extremely facile and warrants further investigation, as does formose synthesis in the presence of congeners such as HCN, NH₃, and inorganic compounds such as borate, sulfide, and sulfite, and the impact of UV and visible radiation on this chemistry.

As mentioned above, the perceived importance of the formose reaction rests mainly on its role in sugar synthesis, which is important in the context of abiotic nucleic acid synthesis. Sugar synthesis, of course, is merely one step on the way to nucleoside, nucleotide, and nucleic acid synthesis, which also may require certain specialized environmental conditions (Fuller et al. 1972), although there are proposed mechanisms for nucleotide formation which do not necessarily depend on direct condensation of the nucleic acid base with a sugar (Powner et al. 2009).

Future Directions

The possible prebiotic importance of formose chemistry has launched a great deal of experimental study of its kinetics, products and robustness in geochemical settings. It is likely there remains a good deal of chemical complexity to yet be revealed in this fascinating reaction.

Formyl Cation (HCO^+)

William M. Irvine

University of Massachusetts, Amherst, MA, USA

Synonyms

HCO^+

Definition

The triatomic ion HCO^+ is one of the most abundant molecular ions in dense interstellar clouds. It is a key intermediary in the production of ► **carbon monoxide**, CO , which is in turn the most abundant constituent of these regions after molecular hydrogen (H_2). The abundance ratio of HCO^+ to its deuterated counterpart, DCO^+ , can provide a measure of the electron density in molecular clouds. HCO^+ is a linear, closed-shell molecule, so that its pure rotational spectrum consists of a series of harmonically related lines, with the lowest transition in the 3 mm wavelength band.

History

In 1970, L. Snyder and D. Buhl reported the detection of an unidentified emission line in the spectra of several interstellar ► **molecular clouds** and referred to the unknown carrier as “X-ogen.”

Laboratory measurements subsequently confirmed that X-ogen was HCO^+ , in agreement with the theoretical predictions of ion-molecule chemistry by W. Klemperer and E. Herbst that this ion should be abundant in such clouds.

Fossil

Emmanuelle J. Javaux
Palaeobiogeology-Palaeobotany-
Palaeopalynology, Geology Department,
Université de Liège, Liège, Belgium

Definition

A fossil is the preserved remnant of an organism after its death. A fossil may be morphological or chemical. A fossil can have various sizes (microscopic to macroscopic) and composition (organic or mineral) and may represent a whole organism, part of an organism, colonial organisms, or the morphological or chemical imprint of an organism or of its activity. The processes of fossilization are complex, and they may lead to the preservation of organisms in their original composition or partially or be completely replaced by another (organic or mineral) material or preserved as a mold or cast or as traces of activity such as footprints, trails, or burrows (“ichnofossil”).

Definition

Fossilization refers to the processes leading to the preservation of traces of life in the geological record. While metazoans and single-cell eukaryotes leave undisputed traces in the geological record in the form of hard mineral parts, the fossilization of microorganisms such as *Bacteria* or *Archaea* or of viruses has long been debated due in particular to the difficulty to recognize unambiguously such fossils in old rocks. ► [Biomineralization](#) controlled or induced by microorganisms themselves seems to be a major process allowing preservation of cell structures and/or of organic molecules.

Overview

The three domains of life can, in principle, be preserved as ► [microfossils](#), depending on the conditions of preservation and their original composition. Most fossils in the Phanerozoic are made of hard mineral parts or imprints of hard mineral parts of metazoans or eukaryote unicellular organisms (e.g., diatoms, foraminifers). Some prokaryotes can also form biominerals that might be preferentially preserved in the geological record (Benzerara et al. 2019). However, we focus here on processes of fossilization of soft tissues and mostly of microorganisms that are more relevant to astrobiology than macroorganisms.

Interestingly, it has been widely suggested that microorganisms were often involved in the fossilization of metazoan soft tissues (e.g., Raff et al. 2006; Iniesto et al. 2015).

There are undisputed fossils of prokaryotes in the geological record, and some have been assigned taxonomic names such as *Girvanella* (Riding 2002). The abundance of these microfossils has varied through geological time. The absence of microfossils has sometimes been interpreted as evidence for abiotic conditions prevailing during the formation of a rock. For example, the absence of microfossils in Archean stromatolites has been used to question their biogenicity (e.g., Grotzinger and Rothman 1996; Brasier et al. 2006). Alternatively, the varying abundance of microfossils has been related to variations of environmental conditions triggering or hindering fossilization (e.g., Arp et al. 2001). It is thus important to understand processes of fossilization in order to identify the main factors controlling the formation of microfossils and better read the paleontological record.

When a microorganism dies, organic molecules and cellular structures can be degraded very rapidly. It is usually thought that enzymes released by dying cells and/or other cells catalyze this process (lysis) and that this results in a rapid cycling of organic matter. However, in some cases, the development of microbial biofilms somehow retards the degradation of organic tissues and may therefore allow more time for mineral precipitation to occur, favoring subsequent fossilization (Iniesto et al. 2016). The molecular mechanisms and determinants of such a microbially mediated protection remain to be understood. Moreover, some organic molecules might be selectively preserved because they are more resistant to this chemical degradation such as polymers forming the cell wall of spores (e.g., sporopollenin, Bernard et al. 2015) or molecules transformed secondarily by chemical reactions such as sulfurization of organic carbon (e.g., Lepot et al. 2009a; Damste et al. 1998) or formation of geopolymers (Vandenbroucke and Largeau 2007). Precipitation of minerals on cells, that is, biomineralization, is another major process that favors fossilization of prokaryotes by armoring

cellular structures against the lytic action of enzymes (Li et al. 2013). A broad diversity of mineral phases can fossilize microbial ultrastructures exquisitely, including phosphates (Cosmidis et al. 2015), carbonates (e.g., Couradeau et al. 2013), or silicates (Zeyen et al. 2015). Several mechanisms can favor mineral precipitation within and/or at the surface of cells and usually involve specific metabolic activities and environmental conditions. For example, it has been proposed that anoxic conditions are necessary for fossilization. The absence of O₂ might indeed limit aerobic respiration, hence degradation or organic matter but is not a sufficient parameter (Allison 1988). In addition to this, anoxic environments are usually rich in metals (e.g., Fe, Mn) and/or sulfides that can precipitate on cells.

Experimental taphonomy refers to fossilization experiments conducted in the laboratory or in the field. Although these studies may not all reflect the full complexity of natural environmental conditions, they may reveal biotic patterns and fossilizable properties that have been overlooked and eventually allow a better understanding of the molecular mechanisms operating during fossilization. First, such studies have shown that fossilization of microorganisms can be achieved in few days or few weeks. For example, exposing bacterial cells to a solution rich in Ca, Fe, or Si can lead to their encrustation in few hours (Toporski et al. 2002; Benzerara et al. 2004a; Ferris and Magalhaes 2008; Miot et al. 2009). Moreover, these experiments help decipher what can be preserved in microfossils, regarding their chemistry as well as their ultrastructure. Cyanobacteria have received particular attention. Intra- and extracellular silicification has been observed. It has been shown that sheaths are preferentially preserved as compared to walls and cytoplasm (e.g., Bartley 1996). Some transformations could be observed including cell collapse, shrinkage and disappearance, trichome disarticulation, varying terminal cell morphology, and rupture of sheath (e.g., Toporski et al. 2002). If precipitation occurs in close connection with the microbial structures and if the minerals are small enough, very fine cellular details can be preserved. For example, a 40-nm-thick cell wall of Gram-negative bacteria can be

fossilized by calcium phosphates (e.g., Benzerara et al. 2004a) or by iron minerals (e.g., Miot et al. 2009). Such a preservation of the 40-nm-thick cell wall of Gram-negative bacteria has also been evidenced recently in phosphorite samples from Morocco dating from the Paleocene (Cosmidis et al. 2013). Embryos of eukaryotes could be preserved as well in the laboratory at different development stages by phosphatization, simulating what likely occurred during the fossilization of the famous ~630 Ma old Doushantuo embryos (e.g., Yin et al. 2007). While some organic carbon might be degraded during these processes, it has been shown that most of it can be preserved within resulting mineralized microfossils (e.g., Benzerara et al. 2004b). The diversity of organic moieties that can be preserved in fossils still seems poorly assessed. Biomarkers, that is, highly resistant organic molecules comprising cell walls, are obvious examples (e.g., Derenne et al. 2008). Some organic geochemistry studies have however shown that additional molecules such as proteins could be preserved more than a 100 million years (Riboulleau et al. 2002). Although they remain difficult to recognize in the geological record, viruses, which have been major players in life evolution (e.g., Forterre 2006), seem to be prone to fossilization under some conditions through permineralization (Perri et al. 2018; De Wit et al. 2015). Interestingly, some taphonomy experiments have been performed on these “organisms.” Biomineralization experiments on viruses show that dissolved iron can penetrate virus capsids and bind to internal sites (Daughney et al. 2004). As a result, virus capsids can serve as nuclei for the growth of iron oxide particles. The resulting morphology differs from abiotic iron oxides and organic molecules, which originally composed the capsids, can be efficiently preserved by the iron minerals that armor them, increasing the possibility of accurately identifying them (e.g., Kaiser and Guggenberger 2000).

After the precipitation of minerals on organic structures, further degradation of morphology and organic molecules can take place. This stage is influenced by mechanical stresses, interactions with fluids of varying chemistries, and metamorphism, for example, an increase in temperature

and pressure. Formation of carbonate nodules has been inferred as an efficient mechanism for fossil preservation (e.g., Muller 1985). Observations of natural samples have shown that fossils can sometimes be preserved even after high-grade metamorphism (e.g., Bernard et al. 2007; Galvez et al. 2012), suggesting that T and P might not be prominent factors in the disruption of microfossils. In contrast, mineral growth/transformation has been shown to be highly damaging (e.g., Oehler 1976). Metamorphic processes take place over much longer timescales, so it is more difficult to simulate them in the laboratory. Some studies have suggested that time and temperature are inherently linked and that aging at low temperature over long timescales can be simulated by shorter aging at a higher temperature (Skrzypczak-Bonduelle et al. 2008). This principle has inspired additional studies aiming at simulating natural fossilization processes in the laboratory (e.g., Picard et al. 2016; Alleon et al. 2017; Cousins et al. 2020). However, while Li et al. (2014) clearly showed with such laboratory experiments, that microbial cell encrustation by minerals may favor preservation of chemical and morphological features upon heating, they also stress on the difficulties to relate experimental conditions directly to geological conditions.

Last, one key problem encountered in the study of microfossils is that relatively complex morphologies can be produced by purely abiotic processes (e.g., Garcia-Ruiz et al. 2003) and can thus make their identification difficult. Laboratory experiments can be of value to identify possible specific features that might be used to discriminate abiotic from biological objects. In addition to morphology, the composition of the organic matter produced by reactions such Fischer-Tropsch has been carefully scrutinized and compared with mature kerogens (e.g., McCollom and Seewald 2007). For example, a combination of infrared spectroscopy (providing an aliphaticity index of the organic matter) and microscale measurements of the carbon isotopic compositions was used by Sangely et al. (2007) to distinguish between biology and Fischer-Tropsch-type reactions as genetic processes for the bitumen found in the Cretaceous uranium deposits of Athabasca. Known abiotic

products that can mimic life morphologies or chemistries include vesicles made in the laboratory from meteoritic kerogen or in other prebiotic chemistry experiments (e.g., Deamer et al. 2006), fluid inclusions, carbonaceous filamentous shapes resulting from migrating organic matter (with carbon isotopic fractionation resembling life patterns) around minerals casts in hydrothermal environments (Brasier 2005; Brasier et al. 2006), aggregates of silica spheres and rods in silica-rich waters of hydrothermal springs, migration of carbonaceous materials along microfractures (Van Zuilen et al. 2007), within or around silica (e.g., Jones and Renaut 2007; Lepot et al. 2009b). Finally, mineralized pseudo-fossils have been produced using a mixture of barium carbonate and silica in laboratory experiments (Garcia-Ruiz et al. 2003) or by reacting sulfides with dissolved organics (Cosmidis and Templeton 2016). In both cases, the resulting auto-assembling, sometimes segmented, filaments contain organic matter and are very comparable morphologically with some geological occurrences.

Basic Methodology

Characterization of field samples using analytical tools at multiscale, including scanning electron microscopy, transmission electron microscopy, Raman spectromicroscopy, confocal laser scanning microscopy, NanoSIMS. Laboratory experiments simulating fossilization, biomineralization, diagenesis, and metamorphism.

Key Research Findings

Fossilization is a very fast process. Fossilization can preserve very fine details and chemical heterogeneities down to the nanometer-scale.

Applications

Search for ancient traces of life on Earth and elsewhere.

Future Directions

Several directions remain widely open: first, an improved characterization of microfossils in ancient rocks which will allow in particular discriminating between genuine microfossils and microfossil-like abiotic features. Most of the oldest traces of life are indeed still debated. The advance of cutting-edge technologies, such as Raman spectromicroscopy (Bernard et al. 2008; Schopf and Kudryavtsev 2009), transmission electron microscopy (e.g., Lepot et al. 2008), focused ion beam milling (Wirth 2009; Wacey et al. 2012), synchrotron-based X-ray microscopy (e.g., Lepot et al. 2009a; Obst et al. 2009), and NanoSIMS (e.g., Oehler et al. 2009), provides analyses of mineral and organic matter down to the nanoscale; this should help in achieving that goal. Second, experimental taphonomy can be developed further, inspired by studies of metazoans (e.g., Briggs and Kear 1993). A wide diversity of biomineralizing microbial systems is now available and can provide pre-fossils. Their extensive characterization down to the nanoscale will offer new insight into what can be potentially preserved in the geological record. In addition, a significant improvement in the design of protocols to simulate diagenesis (in particular, the use of fluids with an appropriate chemical composition), aging, and possibly metamorphism would complement this approach. An ultimate and exciting challenge for this field may take place in several years: assessing the presence of potential fossils of microorganisms in rocks recovered at the surface of Mars and brought back to Earth by the Mars sample return mission.

Fossils, Preserved remains, Impressions, Trace of once-living organism.

History

Herodotus (484–424 BC) studied, among other things, how the Nile slammed again, and obviously he understood the concept of time – something that is very central in geology. More speculative claims, however, were the interpretation of the tertiary nummulites (foraminiferal shells) that he found in the limestone from which the pyramids of Giza were built. He interpreted those who petrified the remains of the lentils that were part of the pyramid builders' meals.

Aristotle (384–322 BC) and his philosophy came to make their mark on geological research throughout the Middle Ages until a time shortly after the Renaissance. He observed fossil fish but did not understand the origin but believed that the

fish migrated along underground streams and became petrified.

In 1027, the Persian physician, astronomer, thinker, and writer Avicenna (c. 980–1037) explained fossils' stoniness in *The Book of Healing*: “If what is said concerning the petrification of animals and plants is true, the cause of this (phenomenon) is a powerful mineralizing and petrifying virtue which arises in certain stony spots, or emanates suddenly from the earth during earthquake and subsidies, and petrifies whatever comes into contact with it. As a matter of fact, the petrification of the bodies of plants and animals is not more extraordinary than the transformation of waters.”

In Europe, however, there was a standstill in the field of geology. Albertus Magno (1205–1280) considered, e.g., that mountain ranges formed when water boiled and the water bubbles petrified. Fossil was explained as “*vis plastica*,” i.e., incomplete attempts to create life from inorganic material.

It was only in connection with the Renaissance that direct observations and experiments came into the picture. Leonardo da Vinci (1452–1519) explained the fossilization and conservation of mussels from northern Italy, which for the most part would still stand today. He also understood that the water surface had a different location than in modern times. However, he did not believe in mountain range folds but considered that the mountains were formed solely by erosion. However, it would take a long time before such theories would be recognized. Fossils were still produced as “*vis plastica*” or simply as “*lusu naturae*” – the waste of nature.

During the seventeenth and eighteenth centuries, it became difficult to maintain Aristotle's teaching about the origin of the stones. However, an attempt was still made to find an explanation in accordance with the Old Testament. It was generally thought that the fossils originated from the biblical flood. The Swiss scholar Johan Jakob Scheuchzer (1672–1733) considered fossils as “*tricks of nature*” or just as leftovers from the flood. He depicted a giant fossil salamander which was found in a quarry as “*Homo diluvii testis*,” i.e., one of those abominable people

whose sins brought the calamity of The Flood upon the earth. Ideas like this were accepted for a long time since it seemed to verify the claims of Christian scripture.

The Danish scientist Nicolaus Steno (1638–1686) although questioned the common “knowledge” at the time, that fossils must have grown in the ground, this since the Bible stated God had created the solid Earth during the first week. He realized that fossils were the remains of once living organisms that had been deposited over time. This contribution to geology has led subsequent scholars to rank him as one of the founders of stratigraphy.

Voltaire tried to explain the fossil animal remains that came to light as remains after picnic meals. However, it was not until the Würzburg professor Johann Bartholomeus Adam Beringer (1667–1740) that the “*vis plastica*” doctrine suffered shipwreck. For many years, Beringer collected a fossil material that became increasingly rare and more sensational; animals, plants, spider webs, planets, comets, and God’s own name in Hebrew, all this was published in a scientific publication *Lithographiae Wirceburgensis* (1726). When he finally saw his own name on one of the stones, he realized that he was affected by the students’ sense of humor. He spent the rest of his life trying to buy back the books he had published, here by the concept of Beringer’s lying stones (*Lügensteine*).

The Englishman William Smith (1769–1839) was an engineer and actually engaged in canal construction, but during his work he discovered that fossils could be used to identify sedimentary layers in different areas. He saw that the fossil-bearing layers formed on the seabed and represented the animal world that lived white for the time being. In 1799, he established a table for the stratigraphy (carbon-chalk) stratigraphy of the sedimentary sequences and the most important fossils in each layer. This was something completely new and Smith’s principle is the basis of modern stratigraphy. Gradually, during this time that followed, one systematically examined sediments and fossils from most places on earth.

Detailed descriptions of fossils already appeared in the late eighteenth century, but it was not really until the nineteenth century that modern paleontology developed. The pioneer in this area was Georges Cuvier (1769–1832), a contemporary of William Smith. He was a comparative anatomist and treated the material as if it were a “living” zoological material and not just as petrifying fossils. Among other things, he studied tertiary vertebrates from the Paris Basin. He explained that successive layers could contain such different fossils that each period in the Earth’s history ended with a catastrophe – this was the basis of the catastrophe theory.

Cuvier found support for his disaster theory in the presence of large moving blocks that were thought to have been moved by large rivers (here the idea of The Flood comes back). He did not believe in evolution, but in innovation after every disaster. He argued that the species had not changed since the Creation. The argument was that each species was so well coordinated, functionally and structurally, that it could not survive significant change. In the last great “catastrophe,” which was paralleled with the flood, one could include everything that is today attributed to the last ice age. It was not Cuvier himself who drew the parallels with the Bible.

Overview

The findings of fossils, remains of earlier life, have through history resulted in a wide variety of explanations: everything from meal leftovers, “nature’s waste,” remains from The Flood of the Bible, to more sensible explanations.

Foton Capsule, Spacecraft

René Demets

ESTEC (HSF-USL), Noordwijk, The Netherlands

Definition

Foton is an unmanned recoverable spacecraft, designed and manufactured by TsSKB-Progress in Samara (Russia). Fifteen Fotons were launched between 1985 and 2007, initially from Plesetsk, later from Baikonur. The launch vehicle is a Soyuz-U. The reentry capsule is spherically shaped with a diameter of 2.3 m. Touchdown in the border zone of Russia and Kazakhstan. Payload consisting of scientific and technological experiments with often significant contributions from Western Europe. Power provided by batteries, flight duration therefore limited to 10–16 days. Orbital parameters: inclination 63°, period 90 min, orbital shape: near-circular, cruising altitude around 300 km. Foton has frequently been used for space exposure studies in astrobiology and astrochemistry (► [Biopan](#)) as well as reentry experiments (► [Stone](#)). Spacecrafts Modified Foton have been launched since the failure of Foton M1 in 2002 at launch. Since Foton M4, which was successfully launched and retrieved in 2014, the spacecraft is equipped with solar panels replacing former batteries.

Fractionation

Jennifer C. Stern

Planetary Environments Laboratory, NASA

Goddard Space Flight Center, Greenbelt, MD, USA

Synonyms

[Differentiation](#); [Disproportionation](#); [Partitioning](#); [Separation](#)

Definition

Fractionation is the partitioning of a chemical species into two or more phases based on its chemical or physical properties. The chemical or isotopic composition of each phase may reflect an enrichment or depletion in one element or isotope with respect to the others, which can yield information about the mechanism of formation. Fractionation can be caused by differences in mass and binding energy and by biochemical reactions, which alter the ratio of one element or isotope to another. For example, fractionation of stable carbon isotopes can provide information on the biotic or abiotic origin of some organic compounds, as photosynthetic reactions process the lighter isotope, ^{12}C , more rapidly than ^{13}C , resulting in enrichment in ^{12}C of its products.

Fractionation, Mass Independent and Dependent

Francis Albarède

Laboratoire de Géologie de Lyon, Ecole Normale Supérieure de Lyon, Lyon Cedex 7, France

Keywords

Isotope · Mass fractionation

Definition

Isotope fractionation is referred to as mass dependent when observed isotopic abundances deviate smoothly and monotonically with the masses of the isotopes from those in the reference material. Both kinetic and equilibrium processes are known to account for this most common form of isotope fractionation. Alternate patterns are referred to as mass independent and are known for O and S in some specific environments and are often related to photochemistry in the solar nebula and in planetary atmospheres.

Overview

Isotope fractionation varies approximately with the difference of the isotopic masses. Using ► [oxygen isotopes](#) as an example, the mass difference $^{18}\text{O} - ^{16}\text{O}$ is +2 and $\delta^{18}\text{O}$ will therefore be twice the $\delta^{17}\text{O}$ (where, e. g., $\delta^{18}\text{O}$ is $[(^{18}\text{O}/^{16}\text{O})_{\text{sample}} / (^{18}\text{O}/^{16}\text{O})_{\text{std.}} - 1]$).

In a $\delta^{17}\text{O}$ versus $\delta^{18}\text{O}$ diagram, all terrestrial samples plot on the same fractionation line with a slope of 0.5. Different planets plot on parallel

fractionation lines, except the Earth and the Moon, which plot on the same line, a strong argument in favor of a common origin for the two planetary objects (the Moon giant impact). Small variations of the slope reflect different conditions of fractionation, notably kinetic and distillation effects. Solar oxygen measured in the solar wind implanted in lunar metallic particles or in the particles collected by the Genesis spacecraft contains a mass-independent ^{16}O excess of 5%.

Mass-independent isotope fractionation (MIF) in the solar system is observed for some elements, and the most noticeable effects occur for O and S. The deviation from the mass-dependent isotope fractionation regime is noted $\Delta^{17}\text{O}$ for oxygen and $\Delta^{33}\text{S}$ for sulfur. The $\delta^{17}\text{O}$ and $\delta^{18}\text{O}$ of calcium-aluminum-rich refractory inclusions (► [CAIs](#)) and chondrules in chondrites tend to plot on a line with a slope of 1.0, instead of the normal slope of 0.5 expected from mass-dependent fractionation. Likewise, the oxygen of some trace atmospheric compounds, notably ozone, nitrate, and sulfate, also plot on a line with a slope of 1. Pre-2.3 Ga sulfur also shows MIF of $\delta^{33}\text{S}$ with respect to $\delta^{34}\text{S}$.

Causes for solar system MIF are not agreed upon, at least not for all the elements. Self-shielding calls for isotope-dependent shifts of absorption wavelengths in the UV range: Dissociation in the gas phase is proportional to the abundance of a particular isotope and not to its mass. Self-shielding upon dissociation of a CO-rich gas was well into the 2010s a popular interpretation of mass-independent oxygen isotope anomalies in the solar nebula. The correlation found between $\Delta^{17}\text{O}$ and excess of neutron rich isotopes ^{54}Cr and ^{50}Ti demonstrated that the deviation of oxygen isotopes from the mass-dependent fractionation regime in the solar nebula can only be explained by nucleosynthetic anomalies. In other words, the different parts of the solar system involve at least three unrelated molecular cloud progenitors: the Sun, which is endowed with a huge ^{16}O excess of about 5%, the inner solar system from Mercury to Mars, and the outer

solar system beyond the asteroid belt. The correlation between $\Delta^{17}\text{O}$ and ^{54}Cr excesses, by showing the heterogeneous nature of the solar nebula, made the classic Laplace theory of the origin of the solar system fall out of favor.

Ozone present in the modern stratosphere blocks solar UV radiation. Prior to the “► [Great Oxygenation Event](#)” at 2.3 Ga, the abundance of O_2 in the atmosphere was low and the ozone layer absent: Photolysis of the tropospheric SO_2 released by volcanic activity by solar UV is thought to have been the cause of the MIF recorded in the $\Delta^{33}\text{S}$ of Archean sulfates and sulfides.

Finally, the finite volume of heavy nuclei and spin-orbit coupling may be additional minor causes of deviation of isotope fractionation patterns from the purely mass-dependent trends.

Fragmentation of Interstellar Clouds

Steven W. Stahler
Department of Astronomy, University of
California, Berkeley, CA, USA

Keywords

Star formation

Definition

The dense cores that form stars through gravitational collapse are embedded in much larger and more rarefied expanses of gas. How the parent ► [molecular cloud](#) produces its substructure of dense cores is the problem of fragmentation. The traditional view is that the parent cloud breaks apart as it collapses in on itself. In numerical simulations, objects resembling dense cores are created in turbulent, collapsing clouds. However, there is little evidence that large clouds are indeed collapsing. If they are not, but are at least temporarily stable, then dense cores must be produced in another fashion, perhaps by the slow accretion of background gas.

Overview

The interstellar clouds that contain young stars are relatively small structures embedded within more diffuse background gas. These dense cores have sizes of about 0.1 pc and masses comparable to that of the Sun. The diffuse parent bodies, known as dark clouds or clumps, have sizes larger by two orders of magnitude and masses of at least 1000 times solar.

It is the gravitational collapse of dense cores that creates the new stars we observe in them. But how are dense cores themselves created? The general, and as yet unsolved, issue of how these substructures arise within relatively large molecular clouds is the problem of fragmentation.

A starting point for many theories is the observed fact that the parent cloud has far too much mass, and is far too cold, to be supported by internal pressure. In the absence of other forces, the object must collapse on itself. The traditional view of fragmentation is that this collapse generates substructure. As the cloud contracts, it breaks apart, producing several daughter clouds. Each daughter, in turn, collapses and breaks up. After a number of generations, fragments with stellar-type mass are produced – the observed dense cores.

Within the last few decades, many theorists have performed numerical simulations of collapsing clouds. The fragmentation hierarchy is not seen. However, if the parent cloud is also turbulent, it may directly create substructures resembling dense cores. Intriguingly, the simulated objects even exhibit the range of three-dimensional shapes of real cores.

Unfortunately, there is little evidence that the larger bodies are undergoing collapse. Observations indicate that the typical age of dark clouds and clumps is 10 million years, an order of magnitude longer than the time for them to collapse. It thus appears that these entities are indeed supported, probably by their internal magnetic fields and turbulent motion.

If the parent bodies are not collapsing, then dense cores must arise in another way. Rather than breaking off from the parent (the top-down view), they may accrete gas from their surroundings (the bottom-up view). The mass of the ► [dense core](#) increases until the object becomes unstable and undergoes collapse. This picture is in better accord with the observation that dense cores themselves appear to be in force balance, at least before they form stars.

Free Energy

Jacques Reisse

Université Libre de Bruxelles, Brussels, Belgium

Definition

Free energy refers to the amount of energy in a system that can be converted to work when the reaction takes place at constant pressure. This amount of energy is necessarily less than the available enthalpy. For chemical reactions taking place at constant pressure (which is frequently the case), free energy refers to the Gibbs free energy. The thermodynamic definition of the Gibbs energy (G) leads to the familiar relation $G = H - TS$, where H stands for enthalpy, T for temperature, and S for entropy.

Free-Fall Time

Steven W. Stahler
Department of Astronomy, University of
California, Berkeley, CA, USA

Definition

The time required for an astronomical object to collapse under the influence of self-gravity is called the free-fall time. A hypothetical gas sphere of uniform density and zero temperature collapses to a point at its center in a finite time. This time is inversely proportional to the square root of the initial density. The free-fall time of real objects can still be approximated from the idealized result. For stars, this time is roughly 1 h. Such objects are normally supported by internal pressure and do not collapse. In this case, the free-fall time is approximately equal to the sound-crossing time and to the period of global oscillations.

Acronyms

Fireball Recovery and Interplanetary Observation Network

Definition

FRIPON is an international ground-based network of dedicated video cameras observing the sky to record tracks of light left by fireballs. The data are gathered in a laboratory in Marseille and then processed to infer the trajectory of the falling object and to determine the possible landing area. The network is designed to initiate field searches in less than 24 hours of ► [Meteorites](#) or other fallen objects. The consortium, beginning as of 2022, gathers 105 video cameras and the contribution of 25 military radars of the GRAVES network (Grand Réseau Adapté à la VÉille Spatiale) spread over 15 countries. Most of the cameras are

in Europe and a vast majority in France. The distribution of cameras on French territory constitutes a network with a mesh of 50–60 km.

History

The project was initiated in 2013 at the initiative of a team of French researchers and supported by a grant from the Agence Nationale pour la Recherche (ANR). This first grant was used to design and standardize the hardware, to set up the network and data processing in France. In 2016, neighbouring countries joined the project which is operational and seeks expansion.

FU Orionis (Object)

Lee Hartmann
University of Michigan, Ann Arbor, MI, USA

Acronyms

FUor FU Orionis (Object)
AU astronomical unit, Earth-Sun distance

Synonyms

[FUor](#)

Definition

FU Orionis objects are very young stars that become extremely bright as a result of sudden accretion of large amounts of gas and dust from a circumstellar disk (Herbig 1977; Hartmann and Kenyon 1996; Hartmann et al. 2016). The main members of this class brighten by factors of 100 or more over timescales of months to years and can take decades to a century or more to fade. During the accretion outburst, the disk itself becomes so luminous that it outshines the central star, and so the visual (and near-infrared) spectrum is dominated by disk emission.

Pre-outburst, the FU Orionis systems are thought to consist of young (ages <one million years), 0.7–0.2 solar mass stars surrounded by a circumstellar disk like those thought to be the sites of planet formation. During the accretion outbursts, as much as 0.01 solar masses (10 Jupiter masses) can be transferred onto the central star. The disk becomes very hot, with maximum surface temperatures ~6000 K at small radii; models indicate that the internal temperatures at the inner edge of the disk are very much higher, 50,000 K or more, due to radiative trapping of the intense release of accretion energy.

The radial extent of the rapidly accreting region is not very well-determined, but it probably extends out to 0.3 AU or so (Zhu et al. 2008), roughly corresponding to the region where the internal temperatures during outburst are thought to reach ~1000 K. These temperatures are high enough to provide the melting of calcium-aluminum-rich inclusions (CAIs) seen in the most primitive chondritic meteorites, and models of marginally gravitationally unstable disks suggest that such particles could be transported outward as far as 10 au (Boss et al. 2012, 2020).

What produces the outbursts is not clear. The large amounts of mass accreted suggest that gravitational instabilities in the disk are responsible, perhaps either by accreting self-gravitating blobs (Vorobyov and Basu 2005) or by heating which triggers magnetic turbulence (Armitage et al. 2001; Zhu et al. 2010; Bae et al. 2013). Continuing infall from remnant protostellar clouds may help keep the disks massive. It seems increasingly

likely that more than one mechanism can be responsible for outbursts, as advances in monitoring broad areas of the sky have turned up many new variables that exhibit considerably smaller accretion events (e.g., Hillenbrand et al. 2018).

Event statistics are uncertain; the FUors, especially the ones with the biggest outbursts, are rare, because the low-mass stars can't spend a lot of time accreting at 10^{-5} – 10^{-4} solar masses per year. Nevertheless, current estimates suggest that at least some stars must undergo perhaps 10 bursts or more (Herbig 1977; Hartmann and Kenyon 1996), with a higher frequency for the more numerous small events. Statistics should improve with increased all-sky monitoring projects, which should help understand the role of accretion outbursts in star formation and thermal processing in protoplanetary disks.

Synonyms

[Buckminsterfullerene](#); [Buckyball](#); [Footballene](#)

Definition

A fullerene is a carbon molecule arranged in the form of a hollow sphere. Any graphene sheet can be closed into a fullerene cage provided that 12 pentagons are inserted into the sheet of condensed hexagonal rings. Only fullerenes having the 12 pentagonal sites fully annealed by hexagonal rings are stable and have been isolated in macroscopic quantity. This is an important rule regulating the fullerene stability known as “isolated pentagons rule” or IPR. The fullerenes isolated in macroscopic quantity are those following strictly the isolated pentagons rule: C_{60} , C_{70} , C_{76} , C_{84} , C_{90} , C_{94} ... Each fullerene contains $2(10 + \zeta)$ carbon atoms corresponding to 12 pentagonal sites and ζ hexagons. This building principle is a consequence of Euler’s theorem (e.g., Kirk 2007; see also Cataldo et al. 2011). Fullerenes can have elements (metals, noble gases) trapped inside the cages, and these molecules are known as endohedral fullerenes (Kroto et al. 1991; Yang and Wang 2014; Popov 2017).

History

The structure of the most common fullerene, C_{60} , was first hypothesized in 1970 by Eiji Osawa in Japan and was the object of topological and theoretical calculations by the Russians I. V. Stankevich, D. A. Bochvar, and E. G. Gal’pern in 1973. Only in 1984–1985, using mass spectrometry, was it possible to observe a series of carbon clusters that were recognized as fullerenes. H. Kroto, R. Curl, and R. Smalley were awarded the 1996 Nobel Prize in Chemistry for their role in the discovery of this new class of molecules. The production of fullerenes in microscopic quantities at first by W. Kraetschmer and D. Huffman in 1990 created a major breakthrough in fullerene science. The fullerenes are named after Buckminster Fuller, an architect who designed polyhedral domes based on hexagonal and pentagonal faces.

Overview

Fullerene C₆₀ is the most studied fullerene. It is composed of 60 sp²-hybridized carbon atoms arranged in a truncated icosahedron geometry resembling a soccer ball. The molecule contains 30 weakly conjugated double bonds located between the hexagons. The diameter of C₆₀ is 700 pm (picometers). All carbon atoms in C₆₀ are equivalent, giving a sharp single signal in the ¹³C-NMR spectrum located at a chemical shift of 143.2 ppm (parts per million by frequency). The mean C-C distance is 141 pm, which is almost same as in graphite (Kroto et al. 1991).

Basic Methodology

Fullerenes are produced by quenching carbon vapor in a helium atmosphere. Carbon vapor can be generated by resistive heating of graphite or in a 40–60-ampere carbon arc. The best yields of fullerenes are obtained at a helium gas pressure between 100 and 200 mbar. Under these conditions, a carbon soot is collected which, when extracted with benzene or toluene, releases 5–10% of its weight under the form of extractable colored matter consisting of a mixture of C₆₀ and C₇₀ fullerenes. C₆₀ is by far more abundant than C₇₀ in the mixture. The two fullerenes can be separated by common chromatographic procedures on an alumina column using hexane/toluene as eluents. Small amounts of higher fullerenes (C₇₆, C₈₄, C₉₀, C₉₄) can be further separated by high-performance liquid chromatography on reversed phase using acetonitrile/toluene as mobile phase. In the extracted soot, fullerenes > C₁₀₀ remain, which can be further extracted with 1,2,4-trichlorobenzene (Taylor 1999). Fullerenes can be produced in relatively small yield also under controlled combustion conditions in sooting flames and extracted with solvents from the recovered soot (Howard et al. 1992). This method has achieved industrial applications (Murayama et al. 2004).

Key Research Findings

Fullerenes were predicted to be present in space (Hare and Kroto 1992) and have indeed been

found. The main sources of carbon dust and molecules in the interstellar medium are the late-type carbon-rich stars (Ehrenfreund and Charnley 2000; Millar 2004), but there is a class of stars, which lies in the transition between the asymptotic giant branch (AGB) and the ► [planetary nebula](#) stage, that was thought as a very promising source of fullerenes. The stars in this class are rather rare, are helium rich, and are extremely depleted in the hydrogen content of their gaseous shells, so that as the carbon vapor is ejected from the star, it cools and forms an ideal environment for fullerene formation (Kroto 2006). In fact, the presence of hydrogen is known to have negative effects on the formation of the fullerene cage and to favor the production of ► [polycyclic aromatic hydrocarbons](#) (PAHs) and other products (Goeres and Sedlmayr 1992, 1993). The prototype of such stars where fullerenes may be present is *R Coronae Borealis* and the corresponding class of RCrB stars (Unsold and Baschek 2002; Kaler 2006). Indeed, C₆₀ fullerene has been found in RCrB stars, but its detection was not easy and its abundance low or negligible, in contrast with the expectations (Garcia-Hernandez et al. 2011).

On July 2010 the fullerenes C₆₀ and C₇₀ were found for the first time around a young ► [planetary nebula](#) of our Galaxy known as Tc1 (Cami et al. 2010). The discovery was made possible through Spitzer infrared space telescope measurements. The detection of fullerenes in that astrophysical object came as a surprise, since it is known that fullerenes are formed only in environments completely free from hydrogen. The fullerenes were detected in the inner core region of Tc1, which turned out to be carbon rich, hydrogen poor, and dusty (Cami et al. 2010). Furthermore, from the spectral signature, it was evident that C₆₀ and C₇₀ were embedded into the carbon dust and not in the vapor phase (Cami et al. 2010). Since the discovery of Cami et al., especially fullerene C₆₀ and sometimes also C₇₀ have been found in many other astrophysical objects, for example, in planetary nebulae belonging to the Magellanic Clouds (Garcia-Hernandez et al. 2010), in proto-planetary nebulae (Zhang and Kwok 2011), and subsequently in a number of planetary nebulae in our Galaxy and in the Large and Small Magellanic Clouds (Garcia-Hernandez et al. 2012). C₆₀

fullerene was detected even in the IC308 star cluster of the Perseus molecular cloud (Iglesias-Groth 2019).

Fullerene C_{60} has been also detected in the interstellar medium and more precisely in the reflection nebulae NGC 7023 and NGC 2023 (Sellgren et al. 2009, 2010).

In the interstellar medium, C_{60} fullerene should be present as a neutral molecule or may undergo ionization to C_{60}^+ . This cation may be responsible for some spectral features in the diffuse interstellar bands (DIBs), absorption bands detected in the spectra of stars in our Galaxy, and beyond (Foing and Ehrenfreund 1994). Further claims for the detection of C_{60}^+ in the ISM seem to confirm once again that this molecule is ubiquitous in space (Berné et al. 2013). Fullerene cations may undergo multiple addition of atomic hydrogen, forming hydrogenated derivatives (Petrie et al. 1995). In 2013 Iglesias-Groth and Esposito reported the detection of C_{60} cation in the protoplanetary nebula IRAS 01005 + 7910 (Iglesias-Groth and Esposito 2013).

In 2016 the C_{60}^+ was unambiguously detected in diffuse clouds through the reddened star HD 183143 through an excellent and high level laboratory research work combined with astrophysical observational data (Campbell et al. 2016; Maier and Campbell 2017). It was firmly confirmed that fullerene cation is the carrier of the DIBs at 957.7 nm and at 963.2 nm (Maier and Campbell 2017).

Neutral fullerenes also add atomic hydrogen easily at very low temperatures (Howard 1993), so that it is reasonable to think that fulleranes, the hydrogenated fullerene derivatives, should be present in the interstellar medium (Petrie and Bohme 2000; Cataldo and Iglesias-Groth 2010).

Fulleranes can be produced in the laboratory under a variety of conditions (Cataldo and Iglesias-Groth 2010). Deuterated fulleranes have also been synthesized. Significant isotope effects both in the photolysis and in the thermal decomposition of fulleranes and perdeuterofulleranes have been observed (Cataldo et al. 2009a; Cataldo and Iglesias-Groth 2010). An enrichment in the deuterium content in fulleranes is hence expected in the space environment. Additionally, fulleranes

release molecular hydrogen under certain circumstances and are thought to play a role in molecular hydrogen formation in space, starting from atomic hydrogen (Cataldo and Iglesias-Groth 2010).

Calculated infrared spectra for hydrogenated fullerenes have been published in comparison with the ► [unidentified infrared emission bands](#) (Webster 1991; Cataldo and Iglesias-Groth 2010). The infrared spectrum of $C_{60}H_{36}$ has also been compared with the infrared features of astrophysical objects like the protoplanetary nebulae (Cataldo 2003). An inventory about fullerenes and hydrogenated derivatives in the interstellar medium and their theoretical spectral properties can be found in the recent works of Iglesias-Groth (2004, 2005, 2006). A connection between fulleranes and the strongest ► [diffuse interstellar band](#) (DIB) known in the optical has also been proposed (Iglesias-Groth 2007, 2008).

The reference infrared spectra of fullerenes and fulleranes (the hydrogenated fullerenes) are now available in a wide range of temperatures useful for searching and recognizing such molecules (Iglesias-Groth et al. 2011, 2012). Furthermore, the molar extinction coefficients and integrated molar absorptivity of these molecules are now available for the estimation of the abundance of fullerenes and fulleranes (Iglesias-Groth et al. 2011, 2012). For an updated view on fulleranes and hydrogen addition to the fullerene cage, it is highly recommended the work of Tanuma et al. (2021).

An important property of molecules of astrochemical interest regards their stability to UV photons. A plethora of organic molecules are today known in different space environments (Ehrenfreund and Charnley 2000; McGuire 2021), some of them known to be the precursors of life. Photochemical processing may lead to the production in space of other interesting molecules from common precursors or may lock certain molecules into dust or dust-forming nanoparticles. In this context, the photophysical and photochemical properties of fullerenes and their hydrogenated counterparts, the fulleranes, are of interest, both for the detection of these species and to estimate their survival and their fate in the harsh space environment. The photophysical properties

Fullerene, Fig. 1 Stick and ball model of C_{60} fullerene

of fullerenes are well known, the photochemistry and the radiation chemistry of these molecules having been explored, revealing a very high stability of fullerenes to both high-energy photons and corpuscular radiation (Cataldo et al. 2009b) (Fig. 1).

Future Directions

The search for fullerenes in various natural environments has been the object of a monograph (Rietmeijer 2006). Fullerenes have been found in the Cretaceous-Tertiary boundary layer, in meteorites, and in organic deposits. The search for fullerenes in space will be intensified (Sellgren et al. 2009; Iglesias-Groth 2007, 2008; Lambert et al. 2001; Clayton et al. 1995; Goeres and Sedlmayr 1993). It will be necessary to record the laboratory spectra in the infrared, the ultraviolet, and the visible of fullerenes and fulleranes, especially at low temperatures, in order to have available reference spectra useful for the research of this class of molecules in space. Moreover, future research in the laboratory will be directed toward higher fullerenes, which until now have been scarcely studied simply because they are not easily accessible.

Fullerenes have been found mixed with PAHs in certain astrophysical environments, and it is

completely reasonable that both fullerenes and PAHs share the same destiny when ejected into the interstellar medium. One interesting aspect of future research regards the reactivity of fullerenes with PAHs. We know already that fullerenes easily merge with linear PAHs to form Diels-Alder adducts known as acenes (Cataldo et al. 2013). The spectra of adducts of fullerenes and PAHs prepared in the lab could be used as reference when searching for evidence of the reactivity of fullerenes with PAHs in space.

Another intriguing aspect regards the fact that fullerenes can be a source of carbon for prebiotic synthesis on icy grains or under other conditions. Fullerene C_{60} is insoluble in water, but if radiolyzed in a water medium or in water-ammonia medium, it yields a polyhydroxylated fullerene, which is completely soluble in water and which can be considered a source of organic carbon for the synthesis of simple molecules precursors of biochemistry (Iglesias-Groth et al. 2013). A mass spectrometric analysis of the radiolysis products of C_{60} fullerene in interstellar ices analogs has revealed the formation of polyynes, ene-yne, and polyenes derivatives (Ursini et al. 2019).

Fumarole

Jörn Helbert

DLR, Institut für Planetenforschung, Berlin, Germany

Definition

Fumaroles (Latin fumus, smoke) are vents from which volcanic gas escapes into the atmosphere. Fumaroles may occur along tiny cracks or long fissures, in chaotic clusters or fields, and on the surfaces of lava flows and thick deposits of pyroclastic (explosive ash) flows. They may persist for decades or centuries if they are above a persistent heat source or disappear within weeks to months if they occur atop a fresh volcanic deposit that quickly cools.

Fumaroles are common on ► [Earth](#); for example, there are an estimated four thousand fumaroles within the boundaries of Yellowstone National Park. The Mars Exploration Rover Spirit has identified possible fumarolic deposits in Gusev crater.

Definition

Fungi are essential drivers of biogeochemical cycles at the Earth surface. They are involved in both rock weathering and neogenesis of minerals, the latter as by-products of their impact during alteration. During biomechanical weathering, fungi can penetrate into minerals forming tunnels and channels. During biochemical weathering, fungi mobilize elements contained in minerals using acidolysis, complexolysis, redoxolysis, and metal accumulation in their biomass. Secondary minerals, such as metal-oxalates, -carbonates, -phosphates, and clays, are also generated by fungi as a result of mineral weathering. Moreover, symbiotic associations involving fungi (mycorrhizae and lichens) play a major role in mineral weathering and soil biogeochemical cycles.

Overview

Fungi are eukaryotic organisms that first appear in the fossil record 1 billion years ago (Loron et al. 2019) in agreement with molecular clocks

(Berbee and Taylor 2010). They are heterotrophic and, as such, are well-known for their role in the decay of organic materials (OM). This ability had made them essential in the biogeochemical cycling of the main elements found in OM, i.e., C, N, S, and P. However, they also play a fundamental role in the cycling of other elements crucial for life, such as Ca, K, Mg, Na, and Fe, and trace elements. Recent research has demonstrated their numerous implications in both mineral weathering and neogenesis (Gadd 2017a, b). Most fungi grow as a filamentous network called the mycelium, which exhibits fractal and three-dimensional properties. For example, filamentous fungi have the ability to extensively colonize mineral substrata and actively modify the mineral-fungal interface. They do this not only to physically expand but also to access macro- and micronutrients. Indeed, they are key players in macronutrients translocation (e.g., Ca, K, Mg, Na, and Fe) from minerals to organisms. In addition, they are involved in the mobility of trace elements in numerous ecosystems, e.g., in boreal forests. Consequently, fungal presence and activity directly alter mineral substrates and contribute to continent weathering on a large scale (Hoffland et al. 2004).

The processes at work during fungal weathering can be divided into two main types of action: biomechanical and biochemical. Biomechanical fungal weathering results from direct and indirect physical attacks. Direct biomechanical attack arises mainly as a consequence of the turgor pressure that is exerted at the tip of the fungal hyphae (Money 2008). This mechanism allows fungal mycelia to penetrate into pores and cracks that are already present in rocks, as well as to dig into minerals leading to the formation of fungal tunnels or channels. By this means, mineral surfaces to be weathered increase, leading to higher surface to volume ratios. Indirect biomechanical attacks result from the attachment of fungal hyphae to solid surfaces. Filamentous fungi produce soluble exopolymeric substances (EPS) in order to adhere to a surface. EPS contains water as well as acidic mucopolysaccharides and some other associated chelating agents. These coupled mechanical and chemical processes

efficiently contribute to the weakening of mineral surfaces, accelerating mineral weathering.

Biochemical fungal weathering is due to the interaction of fungi with mineral surfaces, in order to either access nutrients or colonize new niches that are present in rocks. Fungi use four main mechanisms to mobilize the elements contained in minerals: acidolysis, complexolysis, redoxolysis, and metal accumulation in their biomass. Acidolysis refers to the action of (i) low-molecular weight organic acid (LMWOA) secretion (e.g., citric and oxalic acids; Gadd 1999); (ii) the release of CO₂ through catabolic respiration; (iii) nutrient uptake (e.g., ammonium conversion to nitrate during N uptake); and (iv) thigmotropism, which corresponds to proton excretion at the hyphal tip to survey the topography of the hyphal microenvironment (Bowen et al. 2007). Complexolysis is also associated with LMWOA, as well as to other chelating compounds such as siderophores. Siderophores are organic ligands involved in iron bioavailability enhancement and are extremely diverse in terms of molecular structure (Renshaw et al. 2002). All these compounds facilitate mineral dissolution by sequestering metals mobilized from mineral lattices. Redoxolysis is present in fungi, although it is less common than in bacteria. For example, reduction of Fe(III), Mn (IV), Au(III), and Hg(II) in association with fungi has been reported in several studies (Gadd 2007). The main reason for such reactions is either nutrient uptake or metal detoxification. Finally, fungi are able to immobilize metals within their biomass, either externally (biominerals or metal-chelates) or internally (adsorption to the cell wall, complexed onto cytoplasmic proteins, or intraorganelle accumulations). Similar to complexolysis, this process leads to the displacement of the reaction equilibrium in favor of mineral dissolution (Harms et al. 2011).

Fungal weathering is evidenced by dissolution traces on the mineral surface, which appear as large areas with a different aspect than the original mineral surface (Hoffland et al. 2004). They result from the alteration of the mineral surface after selective ion uptake (destruction of the crystal lattice). Other common traces associated with

fungal weathering consist of marks and imprints of fungal hyphae on the mineral surface (Li et al. 2016), as well as tunneling within mineral substrates (Smits 2006).

Another way by which fungal weathering can be detected is the presence of secondary minerals. Metal oxalates, -carbonates, -phosphates, and clays have been observed in controlled experiments examining mineral weathering as a result of fungal activity. Moreover, metal oxalates and carbonates of fungal origin are regularly documented in natural settings (Gadd 2017a, b). Although many metal oxalates are considered as by-products of fungal weathering, they are mostly observed in laboratory experiments and in specific settings, such as polluted sites. Regarding calcium oxalates (whewellite and weddellite), they represent the most widespread forms of fungal oxalate crystals observed in natural environments. They are associated with litter and wood degradation and also form during the weathering of calcium-rich rocks (Gadd 2006). Carbonate minerals are another form of secondary minerals biomediated by fungi. They have been documented in microcosm experiments as a result of fungal weathering. They are also extremely common in the vadose zone environment (caves and soils) where they appear as needle-fiber calcite and calcitic nanofibers (Bindschedler et al. 2016). Metal-phosphates formation has also been described as a by-product of fungal weathering of minerals containing toxic metals. Phosphate salts with uranium (Fomina et al. 2008), lead (Liang et al. 2015), and copper (Crusberg 2004) have all been observed in fungal microcosm experiments. Finally, clays have also been reported as secondary minerals during soil formation in association with fungal activity. Such secondary layered silicates result from nucleation on chelate complexes that are used as templates for crystal structures (Jackson 2015).

At a global scale, symbiotic associations involving fungi, such as mycorrhizae and lichens, have a major role in mineral substrate weathering and consequently in biogeochemical cycles. Mycorrhizae consist of the association of fungal hyphae and plant roots in soils. They are widespread on land surfaces, and it is considered that

approximately 90% of plants are mycorrhized. Ectomycorrhizae, in particular, have extended mycelial networks actively colonizing mineral substrates at great distances from plant roots in order to transfer nutrients such as P and Ca to their symbiotic plant. This is assumed to significantly contribute to rock weathering and soil formation (Quirk et al. 2012). Lichens are fungi living in symbiosis with photosynthetic organisms (cyanobacteria and eukaryotic microalgae) and are also of major biogeochemical relevance since they colonize about 6% of the continental surface. For example, areas at high altitudes and high latitudes exhibit high densities of lichens. Similarly, all mineral surfaces in urban areas (e.g., buildings) are prone to colonization by lichens.

In addition to this, early stages of biological soil crusts (SBCs) consist in fungal-cyanobacterial associations that are functionally similar to lichens (Belnap et al. 2016). The fungal partners of lichens and SBCs mechanically alter mineral surfaces to adhere to their substrate along with the secretion of large quantities of LMWOA and chelating compounds for nutrient uptake (Chen et al. 2000). Finally, both lichens and SBCs are considered as efficient agents affecting the biogeochemical cycles of nutrients, as they contribute to the formation of podzols in boreal forests (Finlay et al. 2009) and initial soil formation at glacier forefields (Schulz et al. 2013).

In conclusion, fungi are prominent agents of mineral weathering due to their filamentous

Fungal Weathering, Fig. 1 Sketch showing the different mechanisms involved in fungal weathering and their outcomes. (Modified and redrawn from Fomina et al. 2007). Biomechanical weathering results directly from pressure dissolution at hyphal tips and indirectly from chemical dissolution related to hyphal adhesion to mineral substrates through exopolymeric substances (EPS). Biochemical weathering results from acidolysis (e.g., H^+ and LMWOA excretion), complexolysis (e.g., LMWOA and siderophores), redoxolysis, and metal (M^+) accumulation

linked to fungal biomass (either in the EPS layer, adsorbed to cell wall polymers, or stored in vacuoles). Biominerals are also evidence of fungal weathering impact. They may be intracellular, such as $CaCO_3$ in the form of needle fiber calcite, or extracellular in the form of various metal oxalates (the most common being whewellite and weddellite). Nutrient uptake (macro- and micronutrients) is the main driver of mineral weathering, as well as colonization of new physical niches and resistance to toxic metals

nature, ubiquity, and diversity of biochemical and biophysical mechanisms involved in mineral alteration (Fig. 1). Their role in the biogeochemical cycles must not be underestimated.

Definition

Fungi are nonphototrophic, heterotrophic eukaryotic microorganisms that contain rigid cell walls and produce spores. Fungi form a tight phylogenetic cluster.

Overview

Defining fungi within the group of eukaryotes is a complex and difficult task and it is preferable to construct a definition based on their common properties rather than on the differences that separate them from the rest of the eukaryotic species. Their peculiar method of reproduction is perhaps one of the main axis on which it is possible to construct a phylogenetic classification, reflecting, in some way, the mechanisms of evolution of each of the groups of fungi represented on Earth.

Many species behave according to Mayr's species definition, presenting a sexual life cycle where two mycelia having sexually compatible cells join to produce a panmictic population that mates randomly after meiotic division generating a fertile population, while others are parasexual

(i.e., involving nuclear fusion followed by gradual de-diploidization).

In a high percentage of species, this mechanism implies an asexual reproduction system that gives rise to specialized cells known as conidiphores that produce dikaryotic cells by mitosis (only nuclear division) which are able to generate a new organism. When they are isolated in pure culture, the asexual strain, known as anamorphous (i.e., *Aspergillus nidulans*), is obtained by the mating of two anamorphous, while the sexual strain is known as teleomorphous (i.e., *Emericella nidulans*). One species has these two reproductive states (asexual and sexual). These two ways of representation in the world of living beings make it necessary to create two systems of classification, one for each type of reproductive state, knowing beforehand that the one for the sexual cycle is close to a phylogenetic proposal and that the other, based on the forms of conidia production, is rather artificial.

About 120,000 species of fungi have been described to date, although the total estimated number of species is around 1.5 million. The versatility of their “soma,” also named mycelia, which in the case of filamentous fungi are made up of a group of septate hyphae, allow them to be present in all possible ecosystems on Earth. Where they are a minority, it is because this environment has, in fact, been little studied yet. Recent studies of metagenomics report their presence in ecosystems under environmental pressure or in the sea. In recent studies of classification of all described species, six kingdoms have been established. Fungi have been included in the kingdom Mycota, in which seven monophyletic “true fungi” are included: Chytridiomycota, Zygomycota, Endomycota (Yeasts), Ustomycota, Ascomycota, Basidiomycota, and Deuteromycota, all grouped as Eumycota. The organisms known as “pseudo-fungi” are phylogenetically close to Protists and contain the Oomycota and Hyphochytridio-Labrynthulomycota groups.

According to their special way of life, all fungi can be defined by the following characteristics: (1) They are heterotrophs and their nutrition is by absorption. (2) In the vegetative stage, they grow

on or inside the substrate as hyphae forming a mycelium showing internal protoplasmic streaming. Reproductive stages with mobility may occur. (3) Cell wall is generally formed by glucans and chitin and, in some cases, glucans and cellulose. (4) Nuclear status, Eucariota, uni- or multinucleate, the thallus may be homo- or heterokaryotic, dikaryotic or diploid, the last usually of short duration with exceptions in some groups. (5) Their life cycle is simple although in some cases complex. (6) Propagules are typical little spores produced in high amounts. (7) Sporocarps or carpophores can be microscopic or macroscopic, with characteristic shapes. In some groups they are known as mushroom and are limited to differentiation tissues. (8) Habitat, ubiquitous in terrestrial, freshwater habitats and in lower numbers in marine waters, although fungal species have been less studied in this environment. (9) In ecology, they play important roles as saprotrophs, mutualistic symbionts, parasites, or hyperparasites. (10) In pathology, they are the cause of serious pathologies to animals and plants. (11) They have a cosmopolitan distribution. (12) Degradation, they are important degraders of plant eliminate macro-polymers (i.e., cellulose, lignin); of fossil combustibles; “sequesters” of heavy metals and radioactive elements at high concentrations.

In general they are responsible for 75% of the turnover of carbon (► [Carbon Cycle](#)), contributing to the degradation of biomass and facilitating its reincorporation into the vital cycle of terrestrial and aquatic plants. At present, the objective is to promote a new taxonomy based directly on comparisons of selected DNA sequences that encode genes with a conserved biological function, instead of or in addition to phenotypic characteristics. These gene sequences should allow the construction of phylogenetic trees integrating microscopic, ultrastructural, and biochemical data leading to a fuller understanding of fungal taxonomy with monophyletic criteria. Nevertheless, the most reliable current criterion to define a given species continues to be the cross-linking of two sexually compatible monokaryon mycelia to form dikaryotic mycelia able, in turn, to produce carpophores.

Furanose

Ramanarayanan Krishnamurthy, Tammy Campbell and Eun-Kyong Kim
The Scripps Research Institute, La Jolla, CA, USA

Keywords

Alpha- versus beta-configuration · Carbohydrates · Monosaccharide · Five-membered ring · D- or L-chirality · Anomeric carbon · Conformation · Aldehyde · Alcohol

Definition

The term furanose denotes a five-component cyclic structure containing four carbon atoms and one oxygen atom and is generally reserved for the description of the molecular framework in monosaccharides. The furanose ring can be a cyclic hemiacetal of an aldopentose (e.g., ribose in RNA and deoxyribose in DNA) or a cyclic hemiketal of a ketohexose (e.g., fructose).

Overview

Furanose denotes a five-membered cyclic structure, belonging to a class of compounds termed carbohydrates, which are molecules composed

of carbon, oxygen, and hydrogen with the empirical formula $C_n(H_2O)_n$. Furanoses are differentiated by various means, including the carbon framework from which hydroxyl groups are attached, the stereochemistry of the hydroxyl groups at each carbon (R or S), and the conformation of the overall structure (envelope or twist). Furanoses are either assigned a D- or L-configuration depending on the ► [chirality](#) of the stereocenter at the carbon farthest away from the aldehyde.

Furanose form can exist in an equilibrium distribution between a cyclic hemiacetal or cyclic hemiketal and an uncyclized free ► [aldehyde](#) or ketone, respectively. Entropy effects favor the intramolecular reaction of the aldehyde (or ketone) and hydroxyl group leading to the distribution of forms as: hemiacetal >99.99%, free aldehyde ~0.01%, and the hydrate in trace amounts (Drew et al. 1998). The two predominant hemiacetals formed are furanose and ► [pyranose](#). In general, furanoses are kinetically preferred, but thermodynamically less stable than pyranoses. The anomeric carbon produced during cyclic hemiacetal formation is bonded to two oxygens. One oxygen is located inside the ring and the other as a hydroxyl substituent in either endo (beta)- or exo (alpha)-position relative to the ring. These are diastereomers or anomers of furanose and generally have altered ratios due to epimerization in solution.

The variations between the aldehydes, pyranoses, and furanoses are biologically important since nature favors one structure over the other. In the case of aldopentoses, four monosaccharides exist: arabinose, ► [ribose](#), xylose, and lyxose. The equilibrium formation of furanose from each aldopentose varies in solution according to their stereogenic centers. Important keto-furanoses in biology include ribulose and xylulose. Ribulose is converted to ribose in the pentose phosphate pathway which is then used by cells in the synthesis of nucleoside triphosphates and ► [nucleic acids](#).

The molecular basis of why ► [RNA](#) is founded on a ribo-furanose and not a ribo-pyranose

structure (Eschenmoser 1999) is a key question that has been addressed extensively in the field concerning the origins of life. One study revealed limitations of the conformational diversity of canonical nucleic acids by systematically synthesizing alternative nucleic acid structures. Markedly lower level of helicity was exhibited by pentopyranosyl nucleic acids in comparison to ribonucleic acid, lending support to the idea that the pentofuranose structure is responsible for the helical shape of the duplex in RNA and ► [DNA](#) (Eschenmoser and Dobler 1992; Pitsch et al. 2003). Another study explored the assemblage and accumulation of pentofuranoses through a borate-mediated stabilization of cis-diols in furanose form (Prieur 2001; Ricardo et al. 2004). Interestingly, among the four aldopentoses, ribose has the highest percentage of furanose form (Drew et al. 1998). Furthermore, model protocellular membranes exhibit a diastereoselective advantage for ribose in the uptake of carbohydrates from solution (Sacerdote and Szostak 2005). And, more recently, by studying the base-pairing properties of oligonucleotides constructed from ribulofuranose and xylulofuranose and comparing them with those of corresponding RNA sequences, the importance of the role of the furanose-ring structure in controlling the anti-conformation of the nucleobases was demonstrated (Stoop et al. 2013; Krishnamurthy 2014). It was shown that the ribo-furanose structure orients the Watson-Crick hydrogen-bonding face of the nucleobases away from the phosphodiester backbone, while the ribulo- and xylulo-furanose rings reverse this orientation resulting in compromised base-pairing properties.

Together, these findings suggest additional functional reasons for why ribose (in its furanosyl form) may have been selected as the structural basis upon which modern biology is based.

Fusion Crust

Tilman Spohn
International Space Science Institute, Bern,
Switzerland

Definition

A fusion crust is a feature of the external appearance of ► [meteorites](#). It describes a glassy coating of the meteorite. The crust forms as a consequence of the frictional heating and melting of the most external layer of the meteorite as it passes through the atmosphere and descends to the ► [Earth's](#) surface. Most of the melt is lost due to ► [ablation](#). Thus, the fusion crust is mostly about 1 mm thick.

G

Ga

Nicholas Arndt
Emeritus Professor, ISTerre, University Grenoble
Alpes, Grenoble, France

Synonyms

[Giga-annum](#); [Gigayear](#)

Acronyms

Ga, Gyr

Definition

Ga is a common scientific abbreviation for the derived Latin word giga-annum or 10^9 years. Note that the Latin accusative, annum, expresses an absolute age, while the English accusative, years (giga-years), expresses a period of time. It is widely used in fields such as astronomy and geology. For example, the current best estimate for the age of the universe, from the Wilkinson Microwave Anisotropy Probe (spacecraft) data on the cosmic microwave background radiation, is 13.7 Ga, and the ► [age of the Earth](#), commonly taken as the time of the completion of accretion, is 4.56 Ga. In geology, the term is often used to signify time before the present; for example, the

time of the Moon-forming impact is 4.51 Ga, and the age of the oldest rocks at the Earth's surface (► [Acasta Gneiss](#)) is about 4.03 Ga.

Gabbro

Daniele L. Pinti
Geotop, Research Centre for the Dynamics of the Earth System, Université du Québec à Montréal, Montréal, QC, Canada

Definition

Gabbro is a common mafic intrusive igneous rock, chemically equivalent to the effusive basalt or occasionally to a basaltic cumulate. A medium- to coarse-grained, dark-coloured rock, gabbro is composed of Ca-plagioclase and clinopyroxene, with or without ► [olivine](#), orthopyroxene, or amphibole. Earth's oceanic crust is composed of 3–5 km-thick layered gabbro, produced by

crystallization of basaltic magma erupting at the ► [mid-ocean ridges](#), covered by pillow basalts and sediments. Gabbro, and its extrusive equivalent basalt, is common on the Moon Highlands (anorthositic gabbro), Mars, Mercury, many large asteroids, and probably Venus.

Gaia Hypothesis

Ricardo Amils
Departamento de Biología Molecular,
Universidad Autónoma de Madrid, Madrid, Spain

Definition

According to the Gaia Hypothesis, the biosphere and the physical components of the Earth form a complex interacting system that maintains the climatic and biogeochemical Earth conditions in homeorhesis. It was originally proposed by James Lovelock who called it the Earth feedback hypothesis, and it is frequently described as a way of seeing the Earth as a single organism.

Overview

James Lovelock first formulated the Gaia Hypothesis in the 1960s, as a result of his work for NASA on developing methods of detecting life on Mars.

At first, the theory was a way to explain the stable concentrations of chemicals such as oxygen and methane that persisted in Earth's atmosphere. Lovelock suggested that detecting such unstable combinations in other planets' atmospheres was a relatively reliable and cheap way to detect life.

Lovelock tried to explain the existence of a global control system over surface temperature, the salinity of the oceans, and the atmospheric composition suggesting that life on Earth functions as a homeostatic feedback system. He called this self-regulating living system Gaia, after the Greek goddess. Since 1971, the distinguished biologist Lynn Margulis collaborated closely with Lovelock in developing the Gaia Hypothesis, and scientific experiments have provided a number of useful predictions to support the hypothesis, although it has always had highly scientifically respected detractors. After long debate and much criticism, a modified Gaia Hypothesis has found acceptance in the field of ecology. Ecologists generally consider the biosphere an ecosystem, and the Gaia Hypothesis is consistent with today's vision of global ecology, which takes into consideration the interactions between biota, the oceans, the geosphere, and the atmosphere.

Gaia Mission

Alessandro Sozzetti

Istituto Nazionale di Astrofisica (INAF) –
Osservatorio Astrofisico di Torino, Pino Torinese,
Italy

Keywords

Astrometry · Exoplanet · Extrasolar planet ·
Planetary systems

Definition

Gaia is the ► European Space Agency's flagship all-sky astrometric survey. Successfully launched in December 2013, Gaia monitors astrometrically all point sources (► stars, ► asteroids, quasars, extragalactic supernovae, etc.) in the visual ► magnitude range $V = 3\text{--}21$ mag, a huge database encompassing almost 2×10^9 objects. Gaia completed its 5-year nominal mission lifetime in summer 2019 and is now progressing in its extended mission. Using the continuous scanning principle first adopted for ► *Hipparcos*, Gaia **determines** the five basic astrometric parameters (two components of position, two of ► *proper motion*, and the ► *parallax*) for all objects, with end-of-mission precision exceeding that of ► *Hipparcos* by 1–2 orders of magnitude. Gaia astrometry, complemented by onboard spectrophotometry and (partial) radial-velocity information, will have the precision necessary to **revolutionize our knowledge of** the early formation and subsequent dynamical, chemical, and star formation evolution of the Milky Way Galaxy.

Overview

The Gaia mission is the new global, all-sky, astrometric initiative of the European Space Agency (ESA). Its launch occurred perfectly on schedule from the ESA's Kourou site in the French Guiana on December 19, 2013. A Soyuz-Fregat launcher took the Gaia module to a transfer orbit, which in 1 month allowed the satellite to reach its operational environment on a Lissajous orbit at Sun-Earth ► *Lagrangian point* L2, 1.5 million kilometers away from Earth. **After an extended commissioning phase, the mission started nominal operations in June 2014. Gaia monitors astrometrically** all point sources in the visual magnitude range $V = 3\text{--}21$ mag, a huge database of about 2×10^9 stars, a few million galaxies, half a million quasars, and a few hundred thousand asteroids. **Gaia completed its 5 years of operational lifetime in Summer 2019. At the time of this writing, the mission has just entered its third year of extended mission operations.**

As for the observing strategy, Gaia's mode of operation has adopted the principles successfully experimented with the *Hipparcos* mission (ESA 1997). In particular, it continuously scans the sky, implying that all detected objects, irrespective of their magnitudes, are observed for the same amount of time during each field-of-view crossing, with mission-end observing time mainly depending on ecliptic latitude (Lindgren 2010). In this way, it is anticipated that Gaia will determine the five basic astrometric parameters (two positional coordinates, two proper motion components, and the parallax) for all objects, with end-of-mission (sky-averaged) precision between 7 and 25 μas (microarcseconds) down to the Gaia magnitude $G = 15$ mag and a few hundred μas at $G = 21$ mag, depending on color. Red objects are expected to have better astrometry, while that for extremely blue targets is estimated to degrade by a factor of 2.

The main partners inside the Gaia project are (1) the European Space Agency (ESA), which has the overall project responsibility for funding and procurement of the satellite, launch, and operations; of interest is the fact that in this case, satellite procurement includes the payload and its

scientific instruments, unlike ESA's other science missions for which scientific instruments are usually principal investigator led and funded (or, at least, co-funded) by participating national space agencies; (2) *European Aeronautic Defence and Space Company* Astrium, which was selected in 2006 as the prime industrial contractor for designing and building the satellite according to the scientific and technical requirements formulated to fulfill the mission science case as approved at time of selection (ESA 2000); and (3) the Gaia Data Processing and Analysis Consortium (DPAC), charged with designing, implementing, and running a complete software system for the scientific processing of the satellite data, resulting in the edition of the "Gaia Catalogue" a few years after the end of the operational (observation) phase.

DPAC was formed in 2006 in response to an "Announcement of Opportunity" issued by ESA. The consortium lists nearly 400 individual members in more than 20 countries. Six data processing centers participate in the activities of the consortium, which is organized in eight "Coordination Units," each responsible for the development of one part of the software (e.g., core astrometric processing, photometry). The ninth coordination unit (CU9), the last DPAC coordination unit, will be in charge of the design and implementation of the Gaia archive. CU9 was created separately from the rest of DPAC through a specific Announcement of Opportunity by ESA. Most of the financial support is provided by ESA and by the various national space agencies through a legally binding long-term funding agreement, a real first for ESA-run missions.

There is no proprietary period for the scientific exploitation of the data. The final Gaia Catalogue will be produced and immediately delivered to the astronomical community worldwide as soon as ESA and DPAC will agree on the processed data having reached the targeted (science) quality. This catalogue is expected to be ready 3 years after the end of operations. Finally, an intermediate data release (DR) scenario has been established, with a preliminary schedule of four successive intermediate releases of increasingly more complete astrometric, photometric, and

spectroscopic data. The first Gaia DRs, DR1, DR2, and EDR3, have been published in September 2016 (Gaia Collaboration 2016a, 2016b), April 2018 (Gaia Collaboration 2018), and December 2020 (Gaia Collaboration 2021). The full third intermediate data release, DR3, is expected to become available by mid-2022. Photometric science alerts have instead been produced and released since early on during the mission operations. Similarly, near-Earth-asteroid information has been routinely communicated at short notice. Finally, the Gaia mission operations have been officially extended until end of 2022, with the possibility to reach a full doubling of the mission lifetime (until 2024–2025 when the thrusters' fuel is expected to run out). More information can be found in Lindegren (2010), while other organizational details and the latest news on payload and satellite developments are available on the Gaia web pages at <https://www.cosmos.esa.int/web/gaia>.

A combination of an ambitious science case, wishing to address breakthrough problems in Milky Way astronomy, and lessons learned from the Hipparcos experience brought European astronomers to realize that Gaia astrometry needed to be complemented by onboard spectrophotometry and (only for objects brighter than $G = 17$) radial-velocity information. These data will have the precision necessary to quantify the early formation and subsequent dynamical, chemical, and star formation evolution of our Galaxy. **The broad range of crucial issues in astrophysics that can be addressed by the wealth of the Gaia data was initially summarized by Perryman et al. (2001). The ongoing scientific exploitation by the community of the successive Gaia DRs has fully materialized the expectations, with >2300 Gaia-based refereed journal articles, as of August 2021. One of the relevant areas on which the Gaia observations will have great impact is the astrophysics of planetary systems (e.g., Casertano et al. 2008), in particular when seen as a complement to other techniques for exoplanet detection and characterization (e.g., Sozzetti 2010). The first results on sub-stellar companions detected by Gaia astrometry,**

photometry, and spectroscopy will be published as part of Gaia DR3. The focus in the remainder of this section will be on exoplanet detectability and impact on exoplanetary science using Gaia astrometry alone.

Basic Methodology

The problem of the correct determination of the astrometric orbits of planetary systems using Gaia data (highly nonlinear orbital fitting procedures, with a large number of model parameters) will present many difficulties. For example, it will be necessary to assess the relative robustness and reliability of different procedures for orbital fits, together with a detailed understanding of the statistical properties of the uncertainties associated with the model parameters. For multiple systems, a trade-off will have to be found between accuracy in the determination of the mutual inclination angles between pairs of planetary orbits, single-measurement precision, and redundancy in the number of observations with respect to the number of estimated model parameters. It will constitute a challenge to correctly identify signals with amplitude close to the measurement uncertainties, particularly in the presence of larger signals induced by other companions and/or sources of astrophysical noise of comparable magnitude. Finally, in cases of multiple-component systems where dynamical interactions are important (a situation experienced already by radial-velocity surveys), fully dynamical (Newtonian) fits involving an n -body code might have to be used to properly model the Gaia astrometric data and to ensure the short- and long-term stability of the solution (see Sozzetti 2005).

All the above issues could have a significant impact on Gaia's capability to detect and characterize planetary systems. For these reasons, a Development Unit (DU) has been specifically devoted to the modeling of the astrometric signals produced by planetary systems. The DU is composed of several tasks, which implement multiple robust procedures for (single and multiple) astrometric orbit fitting (such as Markov Chain Monte Carlo and genetic algorithms) and the

determination of the degree of dynamical stability of multiple-component systems.

Key Research Findings

Gaia's mode of operation (a signal-to-noise limited survey with uneven coverage, including time sampling and scanning geometry, depending on ecliptic latitude) is such that there cannot be any optimization to the case of extrasolar planets. The fundamental requirement, i.e., to have sufficient astrometric accuracy at magnitudes brighter than $V = 13$, was established at the time of the science case definition. Since little can be done with the photometric and spectroscopic capabilities aboard the satellite, which cannot compete with present and planned ground-based facilities for very-high-precision radial-velocity measurements (Pepe and Lovis 2008) and spaceborne observatories devoted to ultrahigh precision transit photometry (e.g., Sozzetti et al. 2010), the potential contribution of Gaia to exoplanet science must be primarily gauged in terms of its astrometric capabilities.

A number of authors have tackled the problem of evaluating the sensitivity of the astrometric technique required to detect extrasolar planets and reliably measure their orbital elements and masses (Sozzetti 2005, and references therein). The two most recent exercises on this subject (Casertano et al. 2008; Traub et al. 2010) have revisited earlier findings using a more realistic double-blind protocol. In this particular case, several teams of "solvers" handled simulated datasets of stars with and without planets and independently defined detection tests, with levels of statistical significance of their choice, and orbital fitting algorithms, using any local, global, or hybrid solution method that they judged was best. The solvers were provided no information on the actual presence of planets around a given target.

A double-blind test campaign to estimate the potential of Gaia for characterizing planetary systems (Casertano et al. 2008) showed that the following could be accurately modeled: (a) planets having an effect on the astrometric signature (α expressed in μ as) with a value around six times

Gaia Mission, Fig. 1 Exoplanet discovery space for Gaia astrometry, Doppler, transit, and direct imaging techniques. Detectability curves are defined on the basis of a 3σ (standard deviation) criterion for signal detection (except for direct imaging, for which a 5σ threshold is adopted). The purple upper and lower dashed curves are for Gaia astrometry with $\sigma_A = 20 \mu\text{as}$, assuming a $1 M_{\text{SUN}}$ G dwarf primary at 200 pc and a $0.4 M_{\text{SUN}}$ M dwarf at 25 pc, respectively. The two purple solid curves correspond to the expectations from a 10-yr extended Gaia mission. The radial-velocity curves (red lines) assume $\sigma_{\text{RV}} = 1 \text{ m/s}$ (upper curve, typical for HARPS-like instruments) and $\sigma_{\text{RV}} = 10 \text{ m/s}$ (lower curve, typical for ESPRESSO-like spectrographs), $M_* = 1 M_{\text{SUN}}$, and a 10-year survey duration. For visible-light transit photometry (green

curves), the assumptions are $\sigma_V = 5 \times 10^{-3} \text{ mag}$ (upper curve, typical for ground-based transit surveys) and $\sigma_V = 1 \times 10^{-5} \text{ mag}$ (lower curve, typical of the Kepler mission), $S/N = 9$, $M_* = 1 M_{\text{SUN}}$, $R_* = 1 R_{\text{SUN}}$, uniform and dense (>1000 data points) sampling. The upper dashed-dotted curve indicates the detection limits for SPHERE/VLT assuming a 250-Myr, $J = 8 \text{ mag}$ primary at 30 pc, while the lower curve is for a more mature primary (1 Gyr) at the same distance observed by PCS/E-ELT. Pink filled circles indicate the inventory of Doppler-detected exoplanets as of 2015. Transiting systems are shown as light-blue filled diamonds, while the red hexagons are planets detected by microlensing. Solar System planets are also shown as green pentagons. Reprinted with permission from Sozzetti and de Bruijne (2018)

the single-measurement error (σ expressed in μas) and orbital periods shorter than the nominal 5-year mission lifetime and (b) favorable configurations of two-planet systems with well-separated periods (both planets with a period inferior to 4 years, a ratio $a/\sigma > 10$, and redundancy over a factor of 2 in the number of observations). In the latter case, it is possible to carry out meaningful coplanarity tests (relative inclination of more than 10°).

Overall, Casertano et al. concluded that Gaia astrometry could allow the discovery and measurement of massive ► giant planets ($M_p > 2-3$

M_J) with an orbit semimajor axis between 1 and 4 astronomical units (au) orbiting solar-type stars as far as the nearest star-forming regions. Saturn-mass planets with similar orbital semimajor axes around late-type stars within 30–40 pc (see Fig. 1) could also be detected. From these results, using Galaxy models and with the current knowledge of frequency of exoplanets, it is possible to infer the number of planets of given mass and orbital separation that can be detected and characterized by Gaia. Table 1 demonstrates that Gaia's main strength will be its ability to accurately measure orbits and masses for thousands of giant planets

Gaia Mission, Table 1 *Top:* Number of giant planets that could be detected (N_d) and measured by Gaia around stars with $V < 13$ mag, as a function of increasing distance (Δd). Star counts (N_s) are obtained using models of stellar population synthesis (Bienaymé et al. 1987), while the

Tabachnik and Tremaine (2002) model for estimating planet frequency as a function of mass (ΔM_p) and orbital period (Δa) is used. *Bottom:* Number of planetary systems that Gaia could potentially detect and measure and for which coplanarity tests could be carried out successfully

Δd (pc)	N_s	Δa (AU)	ΔM_p (M_J)	N_d	N_m
0–50	1×10^4	1.0–4.0	1.0–13.0	1,400	700
50–100	5×10^4	1.0–4.0	1.5–13.0	2,500	1,750
100–150	1×10^5	1.5–3.8	2.0–13.0	2,600	1,300
150–200	3×10^5	1.4–3.4	3.0–13.0	2,150	1,050
Case			No. of systems		
Detection			~1,000		
Orbits and masses (<15% accuracy)			~400–500		
Coplanarity tests			~150		

and to perform coplanarity measurements of a few hundred multiple systems with favorable configurations.

Sozzetti et al. (2014) revisited the topics of giant planet detection and characterization with Gaia focusing on the sample of nearby low-mass M dwarf stars. They found that, given present-day estimates of the fraction f_p of Jupiter-mass companions to M dwarfs, comprehensive screening by Gaia of the reservoir of M dwarfs within 100 pc could result in ~2600 new detections and as many as 500 accurate orbit determinations. It would then be possible to provide estimates of f_p over ten times more precise than those available to date. Sozzetti et al. (2014) also determined that Gaia astrometry, by precisely measuring the orbital inclination, could alert us of the existence of tens of potentially transiting long-period planets. Finally, they gauged the ability of Gaia to accurately predict the ephemerides of (transiting and non-transiting) planets around M stars and its potential to help in the precise determination of the emergent flux, for direct imaging and systematic spectroscopic characterization of their atmospheres with dedicated observatories from the ground and in space.

Finally, Perryman et al. (2014) instead updated the Casertano et al. (2008) planet yield estimates based on an updated pre-launch astrometric error budget and extending the target magnitude interval to $V < 17.5$ mag.

They estimated that, for a 5-yr mission duration, 10,000–20,000 new giant planets might be discovered by Gaia within 500 pc from the Sun, a number that might as much as triple assuming a fully extended 10-yr mission. Figure 1 shows the expected improvements in accessible discovery space in terms of mass and orbital separation for a 10-yr Gaia mission.

Applications

Gaia’s main contribution to exoplanet science will be its unbiased census of planetary systems orbiting hundreds of thousands nearby ($d < 200$ pc), relatively bright ($V < 13$) stars across all spectral types, screened with constant astrometric sensitivity. **The sample of Gaia astrometrically detected planetary systems around bright stars will be the most amenable for a variety of follow-up measurements for improved system characterization.** The Gaia data have the potential to:

1. Significantly refine our understanding of the statistical properties of extrasolar planets: the predicted database of several thousand extrasolar planets with well-measured properties will allow, e.g., to test the fine structure of giant planet parameters’ distributions and frequencies and to investigate their possible changes as a function of stellar mass, metallicity, and age with unprecedented resolution.

2. Help crucially test theoretical models of gas giant planet formation and migration: for example, specific predictions on formation timescales and the role of varying metal content in the protoplanetary disk will be probed with unprecedented statistics, thanks to the thousands of metal-poor stars and hundreds of young stars screened for giant planets out to a few AU.
3. Achieve key improvements in our comprehension of important aspects of the formation and dynamical evolution of multiple-planet systems: for example, the measurement of orbital parameters for hundreds of multiple-planet systems, including meaningful coplanarity tests, will allow discrimination between various proposed mechanisms for dynamical interaction.
4. Aid in the understanding of direct detections of giant extrasolar planets: for example, actual mass estimates and full orbital geometry determination for suitable systems will inform direct imaging surveys about the epoch and location of maximum brightness, in order to estimate optimal visibility, and will help in the modeling and interpretation of giant planets' phase functions and light curves.
5. Provide important supplementary data for the optimization of the target selection for future observatories aiming at the direct detection and spectral characterization of habitable terrestrial planets: for example, all FGKM stars within the useful distance of ~ 25 pc will be screened for Jupiter- and Saturn-sized planets out to several AU. These data will help probe the long-term dynamical stability of their habitable zones, where terrestrial planets may have formed and maybe found.

Future Directions

An improvement of two to three orders of magnitude in achievable measurement precision, down to the μs level, would allow this technique to achieve in perspective the same successes as the Doppler method, for which the

improvement from the km/s to the m/s precision opened the doors for groundbreaking results in exoplanetary science. Indeed, μs astrometry is almost coming of age. The largest compilation of astrometric orbits of giant planets (in many cases, signposts of more interesting systems!), unbiased across all spectral types up to $d \sim 200$ pc, will allow Gaia to crucially contribute to several aspects of planetary system astrophysics (formation theories, dynamical evolution), in combination with present-day and future extra-solar planet search programs.

Definition

Galactic Archaeology aims to infer the formation, history, and evolution of the Milky Way from hints of the processes undergone in the Galaxy

and left on the stars now observable. Particularly, it focuses on the study of the chemistry, age, spatial distribution, and dynamical properties of the current stellar populations and gas clouds, and their comparison with chemical evolution models and cosmological simulations of galaxy formation.

History

The concept of Galactic Archaeology as the recovery of the Galaxy formation scenario from the detailed observations and characterization of its stellar populations was formally established by Freeman and Bland-Hawthorn (2002). They explained that the loss of orbit-information of substructures that fell into and formed the Galaxy can be partially compensated with the chemical tagging over samples of stars, that is, the identification of stellar populations formed in the same environment through their chemical abundances.

Copious research was made following this approach in the subsequent decades, mainly since 2000 with the arrival of large-scale spectroscopic surveys like the SDSS-SEGUE, RAVE, SDSS-APOGEE, GALAH, and LAMOST. However, an undoubtedly big milestone was achieved with the advent of the Gaia mission and in particular after its second data release on 25th April 2018. This mission provided distances and velocities of thousands of millions of stars in our Galaxy with unprecedented accuracy, revealing the Milky-Way configuration in a great detail and challenging our previous view about the Galaxy components.

Overview

The Universe started 13.8 billion years ago and was chemically composed of H and He, and some traces of Li; 100–200 million years after that, stars began to form, synthesizing chemical elements heavier than H (so-called metals) during their evolution. When stars died, they ejected these elements to the interstellar gas, enriching it with metals. Subsequent generations of stars formed

from such gas with increasing higher metallicity. Stars preserve most of the same chemical composition of the gas where they formed in their atmospheres.

The characteristics of a galaxy, like its mass or the surrounding environment, led to a particular star formation history that determines the galactic chemical enrichment evolution. This enrichment is reflected on the chemical composition of its stars now observable. According to the cosmological Lambda-Cold Dark Matter model, galaxies form hierarchically: small stellar systems form in sub-halos of gravitational potential that surround the main host halo into which they merge. Galactic Archaeology aims to identify such systems, the so-called building blocks of the Galaxy, based on chemical tagging and orbital, age, and spatial distribution of long-lived stars.

The interpretation of the observed stellar properties is performed based on the comparison with chemical evolution models and cosmological simulations of the galaxy formation.

Basic Methodology

Large-scale observational surveys provide comprehensive censuses of spectroscopy, photometry, astrometry, and asteroseismology of stars all over the sky. From such kinds of data, it is possible to measure the location, the orbital motion, the chemical composition, and the age of the stars. These censuses permit to build chrono-chemodynamical maps of the Milky Way with a robust statistical characterization of their stellar population properties and the better definition of their distributions across the Milky Way. The advent of large-scale surveys and the development of telescopes, spectrographs, cameras, and computational resources (and, thus, the accuracy in stellar parameters determination) significantly improved Galactic Archaeology in the last decades.

Some of the most important large-scale surveys that boosted Galactic Archaeology have been: in spectroscopy, at low-resolution, the SDSS, RAVE, and LAMOST, and at high-resolution, APOGEE, GALAH, and Gaia-ESO;

in photometry, 2MASS, SDSS, APASS, Pristine, and SkyMapper; in astrometry, UCAC, PPMXL, Hipparcos, and Gaia; finally, in asteroseismology, the Kepler Mission, K2, and TESS.

In addition, computational techniques developed for managing and processing big data, like clustering algorithms, neural networks, or data-driven modeling, also developed Galactic Archaeology optimizing the exploitation of data analysis.

The combination of spectroscopic, photometric, astrometric, and asteroseismologic products allows to derive the needed inputs for chemodynamical evolution models and estimate the Galactic star formation history. For instance, it is possible to constrain the mass of the stellar system where a stellar population was formed, the time of accretion of this system into the Galaxy, or whether the Galaxy underwent inflows or outflows of gas that boosted or quenched the star formation at different epochs.

On the other hand, the comparison of the observed properties of the Milky-Way with cosmological and N-body simulations that trace the evolution of a simulated galaxy over time allows to infer which accretion history and dynamical processes were able to configure a galaxy with similar properties as ours.

The contrast with external galaxy properties allows to understand the ubiquity of Milky Way characteristics in the Universe and the formation of galaxies based on the unique detailed individual-star analysis only available in the Milky Way.

The combination of all these patches of information builds the puzzle of the Galactic history.

Key Research Findings

The research of Galactic formation and evolution has largely benefited from Galactic Archaeology during the last decades, with some important discoveries summarized below for each galactic component:

Thick and Thin Disks

The galactic disk shows two main structures, a thin disk and a thick disk, both differentiated by

kinematics, α/Fe values, and ages of their stellar contents (see ► [Milky Way](#)). Based on cosmological simulations and the fact that thick disk stars are older than thin disk ones, most models predict that the thick disk formed before the thin disk had formed. Therefore, (i) the oldest stars of the thick disk may have formed in a gas-rich disk during burst of star formation events induced by early mergers. (ii) A fraction of these very old stars were dynamically heated by the last large merger (Gaia-Sausage-Enceladus or GSE; Belokurov et al. 2018; Helmi et al. 2018) of the Galaxy, occurred ~ 11 Gyr ago (Di Matteo et al. 2019; Gallart et al. 2019), and are now part of the stellar halo. (iii) The GSE merger also triggered a short (~ 2 Gyr) star formation event when most of thick-disk stars formed. (iv) The thin disk formed later, with some star formation induced from several gas-rich-smaller mergers. The accreted gas, after cooling down, has led the star formation up to now. (v) The galactic bar and spiral arms could have driven thin-disk stars of different ages from their birth place to other galactic locations.

Galactic Bulge

The Galactic bulge shows different stellar populations but is dominated by metal-rich, high- α/Fe , and old stars. Some of these stars present cylindrical rotation and form a barred structure, and others orbit at high altitudes tracing a box/peanut structure. These stars may have formed in the inner disk, during the first ~ 2 Gyr evolution and were heated dynamically by an early bar. Nevertheless, differences in some chemical elements (e.g., Na and Mn) between the bulge and disk stars point out that the bulge may have formed separately via another mechanism, as strong (poor/rich) gas inflows, mergers of dwarf galaxies, and migrations of clumps through the early disk toward the MW center (Queiroz et al. 2021). Its globular clusters show a tendency to be more metal poor and older than the halo ones. Some of the bulge field stars have likely been members of these globular clusters (e.g., Fernandez-Trincado et al. 2021).

Galactic Halo

It is referred to as the Galactic stellar halo those stars whose orbits differ from the rotating disc, with larger vertical and radial velocities. Thus, they populate a spherical halo that surrounds the disc. The Gaia mission helped to clarify the origin of these stars as, mainly, the remnants of the GSE-accreted satellite galaxy, and the ancient disc stars heated by such merger. Furthermore, other stellar structures have been identified in chemical and dynamical space, but it is still unclear whether they belong to the same accreted structure or are remnants of other less-massive accreted satellites.

Because the dynamical timescales are longer further from the Galactic center, the records of accretion events remain observable for several Gyrs in the halo. Indeed, several substructures like streams of stars have been detected covering the whole sky (Bernard et al. 2016), confirming the predictions of the cosmological paradigm of hierarchical galaxy formation.

Globular Clusters

Globular clusters (GC) are mainly located in the halo and bulge and mostly are constituted by more than one stellar population of metal-poor old stars. They may be fossil cores or lumps of the galactic building blocks that were tidal stripped by the main halo and sub-halos during the galactic accretion. The tidal mechanism and the interaction among the GC stars disrupted clusters, making that some of its stars escaped to the halo and the cluster became more compact. For bigger GCs, the different populations could form in bigger satellites during diverse star formation episodes, before the falling towards the halo. For smaller globular clusters (and bigger ones after being accreted), their stars were chemically auto-polluted due to the own stellar evolution, or polluted by companion stars, due to the high stellar density.

Since Omega Centauri is the most massive GCs in the Milky Way, presents metallicity-differentiated populations, and has a retrograde orbit (its rotational motion is opposite to the rotation direction of most galactic stars);

this globular is one of the best candidates for being a compact and remnant core of an accreted dwarf galaxy. More recently, Massari et al. (2019) proposed Omega Centauri would be the nucleus of the Gaia-Enceladus Sausage satellite galaxy, given its mean age and metallicity.

Future Directions

Up to date, there is still not a complete and consistent explanation about the formation and evolution of the Galaxy in the cosmological framework. Therefore, some directions have already been projected into the future.

In particular, the current instrumentation prevents to observe faint stars and, thus, a comprehensive mapping of the distant Galactic regions and the characterization of external galaxies. In addition, dust extinction hinders the observation of the inner Galaxy. Upcoming surveys aim to defy such limits, with larger telescopes like the LSST, the ELT, or the MSE, and next generations of spectrographs, like WEAVE or DESI. Some of the next high-resolution spectroscopic surveys will be MOONS, 4MOST, and PFS.

From the theoretical side, computer science development is also necessary for improving cosmological hydrodynamic simulations of Milky-Way-like galaxies. In particular, increasing the spatial resolution, including more and better physical processes, and better implementing the inter-dependence of astrophysical processes.

Finally, another future direction concerns the exploitation of the upcoming extremely large multidimensional databases. There are current claims to organize an International Consortium to pursue the optimization of Galactic Archaeology performance in terms of gathering all the information available from different sources in a database, homogenizing the measurements from data obtained by different instrumentation and derived by distinct methodologies, and exploring all the scientific potential of the data. Interdisciplinary work between mathematics, engineering, science, and data inference is desired.

Habitable zone · Intelligent life · Extraterrestrial civilization

Definition

A galactic habitable zone is the putative region inside a galaxy with physical conditions compatible with the origin, development, and long-term existence of life-as-we-know-it. Minimum requirements are the existence of enough heavy chemical elements to form Earth-like planets and a low occurrence of catastrophic events (e.g., supernovae, close stellar encounters) in order to allow the evolution of complex life forms.

Overview

The idea underlying the concept of **galactic** habitable zone (GHZ) is that various physical processes, which may favor the development or the destruction of life, may depend strongly on the temporal and spatial position in a galaxy. For instance, the risk of cosmic explosions (e.g., supernovae, gamma-ray bursts) sufficiently close to represent a threat for life is in general larger in the inner galaxy than in the outer one and so is the metallicity (for astronomers, the abundance of elements heavier than helium) of the interstellar medium, which may be important for the formation of Earth-like exoplanets. Assuming that all relevant factors (hostile or beneficial to complex life) can be properly quantified, one may use models of galactic evolution in order to evaluate the position and extent of the GHZ over time. Preliminary attempts gave

controversial results as to the extent of the GHZ of the Milky Way disk, because of the difficulty in properly evaluating the relevant factors, mainly the chemical requirement to form terrestrial planets.

It is hard to quantify the role of metallicity in planetary formation and even harder to draw any quantitative conclusions about the probability of definitive sterilization of a habitable planet. **In the coming years, ongoing (KEPLER, TESS) and future (LUVOIR, PLATO) exoplanet surveys combined with planet formation studies will help to understand the role of metallicity in planetary formation.**

Life displays unexpected robustness and a cosmic catastrophe might even accelerate evolution toward life forms that are presently unknown. Studies of GHZ focused mainly on the Milky Way disk, while the Milky Way halo (presumably too metal poor to allow for planetary formation) and bulge (presumably too dense to avoid frequent catastrophes there) appear – perhaps incorrectly – as less interesting abodes for complex life. The GHZ has recently been computed using cosmological numerical simulations for different types of galaxies (Forgan et al. 2017; Stojković et al. 2019). Few of those studies include kinematic and dynamic aspects of the stars and their planetary systems. These issues are fundamental to infer galactic regions where potentially habitable planets form, if stars have migrated. In addition, the stability of planetary orbits can be affected by the proximity of stars. The concept of GHZ is much more poorly defined than the one of circumstellar habitable zone. At present, it should be considered, at best, as a broad framework, allowing us to formulate our thoughts about a very complex phenomenon such as life (origin, development, and survival) in a galactic environment.

Definition

A galaxy is a massive, gravitationally bound system of ► [stars](#), which may also include stellar remnants (white dwarfs, neutron stars, black holes), gas, and dust, as well as nonbaryonic dark matter. The morphological classification of galaxies, established by E. Hubble in the 1930s, includes ellipticals, spirals, and irregulars, each class divided in subclasses and going from “early types” (generally more massive and gas poor, which is the case for ellipticals) to “late types” (less massive and gas rich, as the irregular galaxies). Galaxies are generally found in groups (up to a few tens of members), clusters (a few thousands), and superclusters. Our own ► [Milky Way](#), often called the Galaxy, is a large spiral with a baryonic mass of $\sim 5 \times 10^{10} M_{\odot}$, slightly smaller than the largest of the Local Group galaxies (M31 or Andromeda). There is no universally accepted definition of a galaxy, nor a clear lower limit on its stellar mass: some systems characterized as “galaxies” (tidal dwarfs, ultracompact

Synonyms

[Jupiter’s biggest moons](#); [Medicean Stars](#)

Definition

At the night of 7 January 1610 the Italian physicist and mathematician Galileo Galilei (1564–1642) observed the planet Jupiter with a telescope made by him and saw what he thought were three fixed stars near it. In subsequent observations made in the following nights Galileo found that the bright spots were not three but four and not fixed stars but rather planetary bodies that revolved around Jupiter, since their positions related to the planet had changed over those nights. Those four biggest Jupiter’s moons, or Medicean Stars as Galileo named them, are: Io, Europa, Ganymede, and Callisto (today Jupiter registers 50 moons and 16 provisional moons). The Galilean satellites are quite different from each other. Ganymede is the largest moon in our Solar system and is the only moon known to have its own internally generated magnetic field. Io has a volcanic nature. The surface of Europa is mostly water ice (it is believed that it has twice the water existing on Earth), and Callisto shows an extremely heavily cratered and ancient surface.

Galileo Galilei

Therese Encrenaz

LESIA, Observatoire de Paris – Section de Meudon, Meudon, France

Definition

Galileo Galilei (1564–1642) is one of the most famous astronomers over the whole history of humanity. With the telescope he designed, he was able to make major discoveries that supported and reinforced the new heliocentric theory proposed by Nicolaus Copernicus that drastically modified our view of the world.

Overview

Galileo, born in Pisa in Italy, started to learn medicine and then turned to mathematics. After a first stay in Pisa, in 1592 he got a chair of mathematics at Padua University. In 1604, on the occasion of the apparition of a new star in Sagittarius, he gave three public lectures on the “Nova,” showing from the absence of ► [parallax](#) that the star was at a great distance from Earth and thus challenging Aristotle’s views about the unchangeability of celestial bodies.

In 1609, Galileo took advantage of new research about spyglasses in Holland to develop the first concept of an astronomical telescope. In August 1609, he presented the Doge of Venice with his first instrument. In January 1610, with a 20-times magnifying instrument, he made the historical discovery of the four big satellites of ► [Jupiter](#), which he called “Medicean” in honor of Cosimo de Medici, Duke of Tuscany (they are now known as the Galilean satellites). This

discovery, together with the irregular shape of the Moon’s surface and the multitude of stars forming the Milky Way, was reported in the historical manuscript “*Sidereus Nuncius*,” published early in 1610. Still in 1610, Galileo observed Venus’ phases, supporting a heliocentric solar system, moving sunspots, and the changing shape of Saturn that he was not able to interpret, but which was in fact due to Saturn’s rings. These results were reported in Galileo’s *Discourse on Bodies in Water* in 1612 and “Letter on Sunspots” in 1613.

In 1616, after the Roman Congregation of the Index banned Copernicus’s *De Revolutionibus* as being “contrary to Scriptures,” Galileo was forced to abandon his plans for a Copernican treatise. He came back to resume his work in 1623, when Pope Urban VIII, an admirer of Galileo’s work, became elected. However, in 1632, his *Dialogue Concerning the Two Chief Worlds Systems* raised the hostility of the Roman theologians; Galileo was summoned to Rome and put on trial. He was forced to abjure publicly the prohibited claims of the Earth’s motion and the Sun’s being at rest and was sentenced to house arrest. His last manuscript “Two New Sciences,” published in Holland in 1638, was devoted to mechanics.

Among the many discoveries that were made possible by Galileo’s telescope, the discovery of the four Galilean satellites probably had the most important implications for astronomy. In contrast with Aristotle’s doctrine, they demonstrated that there is more than one center of rotation in the solar system. By computing the exact periods and the times of mutual ► [occultation](#) of the four satellites, Galileo provided navigators with a method for measuring the longitude from anywhere at sea. Later, the exact timing of Io’s occultations allowed the astronomer Olaf Roemer to get a first estimate of the speed of light; his measured speed was 30% lower than the presently accepted value.

Galileo Mission

Michel Viso
Innovaxiom, Paris, CX, France

Definition

The ► [NASA](#) Galileo mission was launched from Cape Canaveral on October 18, 1989, on board the Space Shuttle Atlantis. The spacecraft and the inertial upper stage were released and fired for a 6-year trip in the solar system, heading to Venus, then to the Earth to perform three gravity-assisted maneuvers, before finally cruising toward ► [Jupiter](#).

Overview

On December 7, 1995, a Jupiter probe released from Galileo entered the Jovian atmosphere with a parachute and transmitted data, relayed by the main spacecraft, for more than 59 min. Then, using the main engine, Galileo was inserted in an elliptic 2-month-long orbit around Jupiter. During the primary (11 orbits) and the extended (14 orbits) mission, Galileo flew by and analyzed most of the Jovian satellites. The mission

Galileo Mission, Fig. 1 The Galileo spacecraft preparation at Kennedy Space Centre. (Photo NASA)

was extended several more years. Galileo made numerous discoveries about Jupiter and its moons. One of the most striking was the evidence of an ocean below the icy crust of ► [Europa](#). The measures of the induced ► [magnetic field](#) for Europa (as for ► [Callisto](#)) while orbiting through the strong Jovian magnetic field were consistent with the presence of conducting layers. This feature may best be explained by the presence of deep salty liquid-water oceans, for which there was already indirect geological evidence (in the case of Europa, see references). Because of the potential existence of such an ocean, NASA decided to destroy the spacecraft at the end of the mission by entering Jupiter's atmosphere, in order to avoid any possible crash on, and contamination of, Europa. Galileo entered the Jovian atmosphere September 21, 2003, at 19 h 49 GMT after 35 orbits. Europa and its ocean constitute one of the major targets of relevance for astrobiology (Figs. 1 and 2).

Gamma Cephei

Nader Haghighipour
Institute for Astronomy, University of Hawaii-
Manoa, Honolulu, HI, USA

Definition

Gamma Cephei (γ Cephei, γ Cep) is a binary star system in which the primary star, Gamma Cephei A, is orbited by a Jupiter-mass planet.

Overview

In 1988, in an article on the analysis of the measurements of the variations in the radial velocities of a number of stars, Campbell, Walker, and Yang reported an interesting phenomenon: The radial velocity variations of γ Cephei seemed to suggest the existence of a Jupiter-like planet around this star (Fig. 1). This was a very exciting and, at the same time, very surprising discovery. It was

exciting because if true, it would have marked the detection of the first planet outside of our solar system. It was surprising because the planet-hosting star is the primary of a binary system with a separation of ~ 20 AU, a distance comparable to the planetary distances in our solar system.

The moderately close orbit of the stellar companion of γ Cephei raised questions about the reality of its planet. The skepticism over the interpretation of the results (which was primarily based on the idea that binary star systems with small separations would not be favorable places for planet formation) became so strong that in a subsequent paper in 1992, Walker and his colleagues suggested that the planet in the γ Cephei binary might not be real, and the variations in the radial velocity of this star might have been due to its chromospheric activities.

Despite the 1992 article, the search for planets in binaries did not stop. Gamma Cephei was continuously monitored and more precise measurements of its radial velocity variations were obtained. In 2003, 15 years after the first announcement of the planet of this system, these efforts bore fruit, and in an article in *Astrophysical Journal*, Hatzes and his colleagues confirmed the existence of a Jupiter-like planet around the primary of γ Cephei (Fig. 2). The parameters of the system were later refined by Endl et al. 2011 and Benedict et al. 2018. As the planet became real, it

Gamma Cephei,

Fig. 1 Radial velocity residuals for γ Cephei after the subtraction of the second order fit to the original radial velocity data (Campbell et al. 1988)

introduced many challenges to planetary science. Figure 3 shows a schematic figure of this system.

The 2003 confirmation of γ Cephei's planet, and the subsequent detection of giant planets in other moderately close binary stars such as GL 86 (e.g., Stassun et al. 2017), HD 41004 (e.g., Zucker et al. 2004), HD 196885 (e.g., Fischer et al. 2009), and HD 176051 (e.g., Muterspaugh et al. 2010), marked the beginning of a new era in theoretical and observational research on planets in dual-star systems. During the past few years,

much research has been carried out in this area, and a large number of excellent articles have been published on different aspects of observational and theoretical studies of planets in moderately close binaries. For more details, see the book, *Planets in Binary Star Systems* (Haghighipour 2010), the more recent review of Welsh and Orosz (2018) on the binaries in the Kepler data, and check the website <https://www.univie.ac.at/adg/schwarz/multiple.html>.

Gamma Rays

Kazumichi Nakagawa

Sanken, Osaka University, Ibaraki City, Osaka, Japan

Keywords

Electromagnetic wave · Radiation

Synonyms

[High-energy photons](#); [High-energy radiation](#)

Definition

Gamma rays are electromagnetic waves with high photon energy. Gamma rays are emitted (1) via transitions between quantum levels of nuclei and elementary particles, (2) via particle-antiparticle annihilation, and (3) via bremsstrahlung (photon emission due to interaction between the strong magnetic field of nuclei and high-energy particles in the vicinity of the nuclei). Gamma rays interact with matter through (1) photoelectron emission, (2) Compton scattering with electrons, (3) creation of electron-positron pairs, and (4) nuclear photoreactions.

Overview

As the result of the interaction of a gamma ray with matter, the gamma ray photon is annihilated and its energy is transferred to an electron. The

resulting high-energy electron will interact with other electrons in the matter to ionize or excite molecules or atoms and will gradually dissipate its energy to produce large numbers of high-energy electrons in the system. Subsequent radiation chemistry due to these high-energy electrons will be responsible for chemical processes. Chemical evolution or molecular damage are the result of this radiation chemistry. According to Platzman (1962), the magnitude of the radiation chemical effect G due to an electron with initial kinetic energy E_0 is expressed as

$$G \propto \int_{IP}^{E_0} \frac{1}{E} \frac{df}{dE} dE$$

where IP is the ionization potential of the system and df/dE the optical oscillator strength distribution, which is proportional to the absorption cross sections.

In order to evaluate the radiation chemical effect caused by gamma rays, the energy efficiency G -value (number of chemical events per 100 eV absorbed) is essential, instead of the photon efficiency or quantum yield (number of chemical events per one absorbed photon). For radiation chemistry, the magnitude of the G -value should be proportional to the incident photon energy $h\nu$ of the gamma rays because the incident photon energy is divided into the small value of IP . The value of $h\nu/IP$ is about 10^5 in the case of $h\nu = 1$ MeV and $IP = 10$ eV.

On the contrary, for photochemistry in which photon energy is ordinarily smaller than 10 eV, the reaction cannot occur if the photon energy is not resonant with the excited state which is responsible for the characteristic transition.

Chemical effects induced by higher-energy photons such as gamma rays, X-rays, and ultraviolet light are similar to each other. It is known that the chemical effects include decomposition, dimerization, polymerization, and ionization. Gamma ray-induced racemization and decomposition of amino acids was reported by Bonner et al. (1985). Dimer formation of alanine molecules induced by X-rays was reported by Kaneko et al. (2005).

Ganymede

Therese Encrenaz
Observatoire de Paris – Section de Meudon,
LESIA, Meudon, France

Keywords

Galilean satellites

Definition

Ganymede is the third Galilean satellite in terms of its distance from Jupiter; on the other hand, it is the biggest satellite in the solar system: it is bigger than the planet Mercury. Like the other Galilean satellites, Ganymede was discovered in January 1610 when Galileo Galilei first pointed his refractor toward Jupiter. It was named by Simon Marius (1614) after a lover of Zeus, who corresponds to Jupiter in Greek mythology. Ganymede's average distance to Jupiter is slightly above 1 million kilometers or about 15 Jovian radii. Ganymede's density is 1.9 g/cm^3 , typical of a 1:1 mixture of water ice and rocks. Water ice was identified at Ganymede's surface as early as 1971 through ground-based near-infrared spectroscopy.

Overview

The space exploration of Ganymede started with the Voyager 2 flybys in 1979 and was followed after 1995 by the Galileo orbiter that operated until 2003.

The surface of Ganymede, as revealed by Voyager and Galileo images, is composed of dark and bright terrains. The old dark terrains are heavily cratered and made up of patchy features of different albedos; the dark material probably corresponds to organic deposits provided by asteroid and comet impacts. The dark regions are fractured by tectonic activity and impact craters, many of them being the signature of the ► [late heavy bombardment](#). Bright terrains show smooth, young areas with grooves and stripes resulting from tectonic activity. These terrains cover three quarters of Ganymede's surface and seem to have been resurfaced mostly by tectonic activity and also partly by active volcanism (possibly ► [cryovolcanism](#)).

The unexpected discovery of an intrinsic magnetic field on Ganymede, by the radio science instrument and the magnetometer of the Galileo mission, strongly suggests that the satellite's interior is differentiated and contains a melted iron nucleus at the center. This magnetic field induces a small stable ► [magnetosphere](#) 5000 km in radius where high-energy particles, radiation belts, and auroras have been observed. Ganymede's magnetosphere, generated by its magnetic field, is in electrodynamical interaction with the Jovian magnetic field through a permanent magnetic reconnection. It acts like a shield that allows the existence of an extended ionosphere, uncompressed by the Jovian magnetic flux.

The interior of Ganymede appears to be differentiated in four layers, with a central metallic core, a silicate mantle, a deep layer of soft ice, and a water ice crust. According to models, a liquid layer of salted water could be present below the surface, sandwiched between two layers of ice. Convection through the icy outer layer transfers the internal heat to the surface. The internal heat comes from radioactive elements within the silicate mantle, from gradual cooling, and possibly

from tidal heating (although less efficiently than in the case of ► [Io](#) and ► [Europa](#)) in Ganymede's past history.

In 2012, ESA selected a space mission devoted to the exploration of Ganymede and the Galilean satellites, with the main purpose of exploring habitability conditions in icy moons. The JUICE mission (JUperiter and ICy moons Explorer) is planned for a launch in 2022. It will approach Jupiter in 2031 and, after a series of flybys, will enter the orbit around Ganymede in 2034 for an in-depth monitoring of the satellite.

Definition

Gas chromatography is a laboratory analytical method for separating volatile components of a mixture as they are passed in a gaseous mobile

phase past a stationary phase or through a column. Separation of molecules is based on differences in the affinity of species for the mobile and stationary phases, which may be influenced by polarity, molecular weight, and volatility. Gas chromatography is often coupled with a detector to quantify and/or identify molecular species. Detection methods include flame ionization, thermal conductivity, and mass spectrometry. Gas chromatography has been used for organic analysis on Mars missions, including ► [Viking](#) and the 2011 Mars Science Laboratory (MSL).

Gas Giant Planet

Daniel Rouan
LESIA Observatoire de Paris - PSL, Meudon,
France

Definition

A Gas Giant Planet is an expression often used to designate the class of extrasolar planets that are of a type analog to the most massive giant planets in the Solar System, Jupiter and Saturn. They are characterized by a big mass (say larger than 100 times the Earth's mass) which implies that they must have an extended gaseous envelope and a rather low density. Indeed, in the various cases where both the mass and the size were measured, massive exoplanets feature a density well within the expected range where are found the solar system's giant planets ($0.7\text{--}1.7\text{ g cm}^{-3}$).

Gas-Grain Chemistry

Steven B. Charnley
Solar System Exploration Division, Code
691, Astrochemistry Laboratory, NASA
Goddard Space Flight Center, Greenbelt,
MD, USA

Keywords

Molecular clouds · Interstellar chemical processes

Definition

Gas-grain chemistry is the study of the chemical processes involving solid dust grains embedded in interstellar/circumstellar gas. Generally, these are loss of atoms and molecules from the gas to the grains, catalytic reactions on surfaces, and return of surface species to the gas phase.

Overview

There are four basic processes: (1) Gaseous atoms and molecules collide with, and stick to, dust grains at low temperatures. The net effect is the depletion of these species in the gas. (2) Adsorbed surface species can migrate, meet, and react leading to new ► [radical](#) and closed shell molecules. Such reactions lead to the conversion of hydrogen atoms to molecules and to the growth of ice mantles on the grain cores. These ices are dominated by water and also contain CO, CO₂, methanol, methane, and ammonia as well as more complex organic molecules. (3) The third is desorption and the consequent return of surface species to the gas. Several processes can remove material from the icy mantles, including photoejection by UV photons, thermal evaporation due to grain heating by cosmic ray impacts or by photon absorption near ► [protostars](#), and ► [sputtering](#) in ► [shock waves](#). (4) The last is the chemistry in the hot gas into which whole or partial removal of the ice mantles has occurred. In this case, it is possible to synthesize many even

more complex molecules by gas-phase ► [neutral-neutral](#) and ► [ion-neutral reactions](#).

Gaspra

Stefano Mottola
German Aerospace Center (DLR), Institute of
Planetary Research, Berlin, Germany

Definition

(951) Gaspra is a main-belt asteroid named after a Crimean town located on the Black Sea. It was the first asteroid to be visited by spacecraft, when the NASA Galileo probe approached it on its course to Jupiter. The analysis of the Galileo images revealed a body approximately $18 \times 10 \times 9$ km in size, with an irregular shape and with a comparatively young surface age between 30,000 and 300,000 years. The body probably originated in a disruptive collision that created the Flora asteroid family, which is believed to comprise about 10^3 objects. Gaspra is classified as an S-type asteroid,

and its surface displays the spectral signature of mafic minerals. Galileo images confirmed the presence of subtle color variations across its surface, which had been previously detected by ground-based observations and which are interpreted as the manifestation of downslope movement of regolith.

Definition

In chemistry, gas chromatography/mass spectrometry (GC/MS) is an analytical method that combines a gas chromatograph and a mass spectrometer. GC/MS was first developed in the 1950s by Gohlke and McLafferty. The gas chromatography uses a capillary column, which may have variable column dimensions (length and diameter) and stationary phase attributes (composition and thickness). The differences in the chemical properties between the molecules in a mixture cause them to migrate with different velocities as they travel the length of the column. As the molecules exit the GC, they are fed into the mass spectrometer where they are ionized and detected using their mass to charge ratio.

These two components, used together, allow a much more precise identification of compounds than would be accomplished using either instrument alone. Sometimes two different molecules can have similar retention times, as measured by GC, or have a similar mass spectrum, but it is extremely unlikely that two different molecules will have the same GC and MS response. Often a third dimension is added to GC/MS analysis, either an extra GC column in GC/GC/MS or an extra MS dimension in GC/MS/MS, both of which further refine the quality of analysis.

Several GC/MS instruments have been sent on space missions. The Viking landers both carried GC/MS instruments to Mars and the Huygens probe studied the atmosphere of Saturn's moon ► [Titan](#) using GC/MS. However, the American Pioneer and Russian Venera 11 and 12 landers analyzed Venus' atmosphere using GC and MS separately.

[General Circulation Model](#), [Global Climate Model](#)

Definition

A General Circulation Model (GCM) is a three-dimensional numerical model of the atmosphere of a planetary body, based on universal physical equations. It aims to simulate all the physical processes in an atmosphere, such as the air motions, temperature structure, or cloud formation. The development of a GCM usually requires extensive amounts of work. GCMs are a cornerstone in the fields of meteorology, weather forecast, and climate sciences. In particular, a GCM is a tool of choice to obtain hints on the possible climate for atmospheres distant in space (extraterrestrial planets) and time (e.g., early Earth).

History

The development of a numerical model of the atmosphere has long been driven by the need to predict weather. In the early twentieth century, Richardson attempted to integrate the equations governing the atmospheric motions by hand, and failed spectacularly because high frequency waves – that could not be handled in his numerical scheme – were present in the initial conditions. With the advent of computers, the first numerical weather predictions were made in 1950 with operational real-time forecast in 1960s, and such subsequent efforts became a great incentive to develop supercomputers for GCMs (Kalnay 2003).

While GCMs were initially developed for weather purposes (hence their initial name “General Circulation Model”), they became a crucial aspect of climate projections to assess climate change and were eventually dubbed “Global Climate Model.” GCMs have become key for revealing the mechanisms and the expected impacts of climate change and thorough, vast efforts of intercomparison of the most advanced GCMs are regularly conducted to assess their accuracy (Eyring et al. 2016).

The adaption of Earth GCMs to extraterrestrial atmospheres was first conducted for Mars (Leovy and Yale 1969), with tremendous success in predicting the global circulation patterns and

temperature structure before detailed observations became available. Later on, successful adaptations to other planets and moons in the Solar System (Venus, Titan, Jupiter, Saturn, Triton, and Pluto) confirmed that GCMs are able to catch the main features of any planetary climate. This led to the exploration of the habitability of Earth and Mars and their distant past, and the climate of exoplanets, for which observations are very scarce or nonexistent.

Today, a plethora of GCM codes exist, developed and maintained by various research teams all over the world.

Overview

A GCM is a numerical model of the atmosphere and possibly other systems, such as the ocean, the land, the surface and sea ice, or the upper atmosphere. It has been applied for Earth and all planetary bodies with an atmosphere. GCMs are very important, and often indispensable, tools to assess the palette of climates of a planet or a moon. They provide crucial information for worlds difficultly accessible (Solar System planets), completely out of our reach (ancient or future climates, exoplanets). Although GCMs are based on the universal laws of physics, they are perfectible and have been increasing in complexity and capability, notably to address the habitability of distant worlds.

Basic Methodology

A GCM is a numerical model built on the universal laws of physics, which ultimate purpose is to build a virtual planet able to give a realistic view of the climate of any planetary body. At the core of a GCM is the atmosphere, made of two main distinct components: a dynamical core (dubbed the “dynamics” part) and physical parameterizations (the “physics” part). The dynamics part numerically solves the Navier-Stokes equations, whereas the physics part takes into consideration all other physical processes taking place into the atmosphere. The physics part generally includes

the radiative transfer of gas and aerosols, convection, cloud formation, chemistry, and exchanges of energy and materials with surface. The division between dynamics and physics allows scientist to run each part independently for model development, validation, or simplified atmospheric modeling. This modularity also opens the possibility to swap parts of independently developed GCMs to further develop and validate models. A GCM can be coupled with other components of the climate system, for instance with numerical model for the oceans, atmospheric chemistry, thermosphere, surface processes, or biosphere.

Dynamics

The primitive equations are a set of equations that described the motions of an atmosphere, by the conservation of momentum, energy, and mass, and an equation of state. The primitive equations are derived from the Navier-Stokes equations, with the approximation of a thin, rotating spherical shell (e.g., Kalnay 2003). This assumption is usually true for most planets, but may be challenged in certain cases, such as for Titan with a vertically extended atmosphere compared its radius.

The primitive equations are discretized either on a spectral or a spatial grid to form the dynamical core. For a spectral grid, the equations are decomposed in spherical harmonics, the resolution being defined by the highest specified harmonics. For a spatial grid, the most convenient choice is a latitude-longitude grid. Other options for the tessellation of the sphere are possible, such as an icosahedral grid. The advantage of a spectral grid over a spatial one is that there is no particular point on the planet, unlike, e.g., the singularity at the poles for a latitude-longitude grid that requires filtering at high latitudes. However, in the case of a spectral grid, a conversion to a from a spatial grid is necessary to communicate with the physics anyways.

The typical horizontal resolution of a GCM is a few hundred kilometers or more, making the hydrostatic equilibrium a reasonable assumption. Under that assumption, pressure monotonically decreases with altitude and therefore forms a natural vertical coordinates system. The hydrostatic

equilibrium is not valid for high-resolution models that can be used for weather prediction on Earth, or the details of the regional circulation on Earth and other planets.

Physics

While the dynamical core simulates the atmospheric motions, physical parameterizations are required to simulate all other atmospheric processes. Unlike the primitive equations of the dynamical core, the physical parameterizations are by definition not explicitly solved because they would require an unrealistically high spatiotemporal resolution for a GCM. Instead, they mimic the overall effect of a physical process at the GCM resolution – typically a few hundred kilometers and ~10 min timestep – guessed and calibrated from the universal laws of physics. Physical parameterizations are implemented for a vertical, one-dimensional column, as they do not require horizontal motions that are mostly driven by the atmospheric circulation, and dealt with the dynamical core. Therefore, the physics can be simulated as a stand-alone 1D model, and it gives GCMs a natural framework for parallel computing. The main physical parameterizations used in GCMs are radiative transfer, convection turbulence, clouds and aerosols, exchanges with the surface, and others.

Radiative Transfer

The most straightforward approach for calculating the heating and cooling rates for each gases and aerosols in an atmosphere is to use a line-by-line code, but this approach is too computationally intensive for a GCM. Instead, a limited number of infrared and visible bands are defined and carefully selected for a given atmospheric composition and aerosols, to statistically represent the photon behaviors for each band based on a line-by-line code. Another technique, called “correlated-k,” consists of approximating the line-by-line calculations by an analytical solution of spectral lines ordered by intensity. This later solution is more versatile than the band model and can be adapted to a cocktail of different atmospheric compositions.

Convection Turbulence

Convection and turbulence are processes occurring at a smaller scale than most GCMs resolution. They play an important role as they are a strong contribution of the energy and materials redistribution on the vertical scale by mixing. Theory, measurements of Earth atmosphere, and high-resolution numerical models constitute the source materials for designing parameterization schemes that aims to predict how vertical mixing occurs on the average on a large scale in various atmospheric conditions.

Clouds and Aerosols

The local presence of clouds and aerosols depend on transport, done by the dynamical core, and on microphysical processes. The latter are controlled by processes at a microphysical scale for clouds (nucleation, sedimentation, coagulation, chemical reactions) and solid aerosols (saltation, lifting) that require simplifications and approximations on a large scale. The accuracy of this parameterization for determining the cloud and aerosols properties is crucial for the radiative transfer calculations that depend on it.

Exchanges with the Surface

The surface exchanges heat and matter with the atmosphere. Heat conduction in the ground is explicitly solved. Ice and liquids at the surface can be a major source of volatiles in the atmosphere (e.g., CO₂ and water at the poles of Mars), and the changes of phase at the surface must be accounted for. More importantly, the horizontal transport of heat by an oceanic circulation, or mass by glaciers, requires specific models to be coupled to the GCM.

Others

It can be necessary to take into account photochemical reactions for some atmospheres (e.g., the sulfur cycle and production of clouds on Venus, the methane cycle on Titan).

In the upper atmosphere, particular thermodynamical processes play an important role, such as UV absorption, molecular conduction, and non-local thermal equilibrium effects on the radiative balance (Fig. 1).

Key Research Findings

Considerable amount of findings have been made by GCMs in numerous scientific fields since their inception in the 1960s, far beyond the scope of this entry. Nevertheless, it is worth mentioning among this wealth of findings some key examples of their application to extraterrestrial planets and ancient climates. They are examples of studies which have greatly contributed to the advancement of our knowledge of habitability on Earth and other planets.

First, GCMs have revealed the circulation of terrestrial planets and gas giants in our Solar System. Based on the simulations of a Mars GCM with a treatment for photochemistry, the observations of methane in the Martian atmosphere were deemed incompatible with all the known chemical processes and source estimates (Lefevre and Forget 2009). Moreover, GCMs are generally able to reproduce the superrotating circulations of Titan and Venus, but the variable results across models do not permit to conclude on the mechanism creating superrotation (Read and Lebonnois 2018). The atmospheres of gas giants can also be simulated by a GCM, with a boundary at an arbitrary pressure level instead of a surface. Spiga et al. (2020) reproduced Saturn's jets, revealing the roles of eddies and seasonal cycles in its atmosphere (Fig. 2). These simulations require a higher computational capability than for their terrestrial counterparts due to the greater size of the gas giants.

Second, the habitability of planets in the Solar System have been extensively studied with GCMs. For instance, adapting a GCM to Venus ancient conditions, Way and Del Genio (2020) found that it could have been habitable in 3 billion years ago. Similarly, Yang et al. (2014) showed that Venus could be habitable today under with its slow rotation rate, under the conditions that enough water is present in its atmosphere to form clouds on its dayside and cool the surface. To this date, GCMs simulating the climate of early Mars (3–4 billion years ago) have struggled to reproduce the conditions necessary for the warming inferred from surface geomorphological features (Wordsworth 2016),

GCM, Fig. 1 Main components usually modeled in a Global Climate Model

leaving the mystery of the past habitability of Mars still unresolved. Simulations of the recent climate changes driven by obliquity on Mars showed that water glaciers used to build up on the flank of equatorial volcanoes a few million years ago (Forget et al. 2006). One-dimensional atmospheric simulation of a column of Earth's atmosphere initially showed that Earth will not be habitable within a few hundred millions years. Taking into account the three-dimensional circulation, GCM simulations instead revealed that Earth will remain habitable until at least another billion years as the sun luminosity increases, before its atmosphere enters in a runaway greenhouse (Leconte et al. 2013). All in all, these studies suggest that the notion of a habitable zone is a complex, multi-factorial concept for which the climate plays a key role, with GCMs being used to explore this space of possibilities.

Third, GCMs are also a crucial tool to gain insight on the conditions reigning at the surface of exoplanets. As an example, the climates of close-in tidally locked planets orbiting M dwarfs have been explored for Proxima Centauri b, showing that many different climates are possible based on the assumptions made on the main atmospheric properties, and that some of them were habitable (Turbet et al. 2016). In the same vein, several planets of the TRAPPIST-1 system were found to be habitable thanks to a GCM (Turbet et al. 2018). Coupling an atmospheric model with an ocean one including sea ice, Yang et al. (2020) stressed the importance of coupling advanced models to assess the climate of exoplanets. Besides their climate, GCMs can also give crucial information on the planetary state. Leconte et al. (2015) found that with as little as 1 bar of surface pressure, the atmospheric torque exerted on

GCM, Fig. 2 Examples of GCM outputs. (a) Temperature (colors), winds (contours and arrows) of Mars (Toigo et al. 2012). (b) Potential vorticity of Saturn (Spiga et al. 2020). (c) Surface temperature of an exoplanet orbiting a M dwarf (Bin et al. 2018)

the solid body is sufficient to drive a planet out of synchronous rotation, despite its close orbit to its star.

While a GCM cannot, is not designed to, provide an accurate prediction for distant or ancient climates, the use of GCMs beyond Earth’s present-day climate have revealed universal patterns of circulation (Hadley-like cells, jets), and are an unique tool to dwell on past and future climates, and on synchronously rotating atmospheres, that have not equivalent in our Solar System.

Applications

Comparing observations to GCMs in a mathematically optimal way is done by a technique called “data assimilation,” in which sets of observations are extrapolated with a GCM. Data assimilation is the keystone of weather prediction (Kalnay 2003), and, outside of Earth, has been applied to Mars (Lewis et al. 2007) and Venus (Sugimoto et al. 2019) so far, given the increasing amount available data for those two planets.

As observations of exoplanets increase in accuracy and quantity, GCMs provide light curves for characterizing the atmospheres of exoplanets in order to probe their atmospheres and discriminate between different climate scenarios.

Future Directions

With their ever-increasing complexity, GCMs are poised to head towards systematic coupling of their atmospheric part with ocean, land, ice, and chemical models. The increase in resolution is also a trend in climate modeling, bridging the gap between regional and global models, allowing for more accurate parameterizations, and even removing the need for some of them. In that regard, GPU computation is an interesting alternative to the usual CPU one.

Definition

Various definitions of the term “gene” occurred and still coexist. Genes are the units of heredity, and this remains true since the pioneering contribution of G.J. Mendel in 1866. ► [DNA](#) is the substrate of heredity, as it was shown by O.T. Avery and his collaborators in the 1940s; thus, ► [genetics](#) and molecular biology have been able to localize genes on this molecular

substrate. Nevertheless, some hereditary information lies also outside the classical or “true” genes. In cells, the classical genes are segments of their DNA genome that can be transcribed into a messenger ► **RNA**, which will be finally translated into a protein, a ribosomal RNA, a transfer RNA, or other kinds of RNAs. Viral genes are fragments of their DNA or RNA ► **genome** that, in most cases, code for the structural or regulatory proteins that will be expressed by the molecular machinery of the infected cell.

Overview

Inheritance in organisms occurs by means of factors or “determinants,” as first concluded by G.J. Mendel in his classic experiments aimed at studying the segregation of heritable traits in peas and other garden plants. Later on, the Mendel’s factors were called “genes” and assigned to particular positions or “loci” on the chromosomes and DNA molecules. The different versions of the same gene are called alleles and, in diploid species – those showing two copies of their genetic material – one allele is inherited from each parent. Diploid organisms can be homozygous for a given gene if they contain two copies of the same allele or heterozygous if they possess a copy of two different alleles (Watson et al. 2008; Lewin 2008).

Genes are specific functional units of a genome potentially transcribed into RNA which possibly will code for a protein. In the decade of the 1940s, it was clear that specific genes code for specific proteins, thus leading to the so-called “one gene-one enzyme” hypothesis. The determination of the ► **genetic code** permitted molecular biologists to unveil the correspondence between coding nucleotide triplets – called ► **“codons”** – in either the DNA gene or the transcribed mRNA and the amino acid they specify. It was further demonstrated that the majority of eukaryotic genes – and a low number of the bacterial and archaeal ones – are not collinear with their protein products. Instead, they are split into segments called ► **“exons”** that code for different protein

fragments. Exons are separated by intervening sequences called ► **“introns”** (Roy and Gilbert 2006). After the ► **transcription** of the gene, a reaction called “RNA splicing” – either protein-catalyzed or autocatalyzed by the intron – allows for the excision of the introns and the covalent joining of the exons in a mature RNA molecule. If such a mature RNA is an mRNA, further posttranscriptional modifications are needed – including capping and polyA addition – before becoming ready to be translated into the coded protein. Due to their mosaic structure, discontinuous genes may code for more than one protein if alternative splicing of their pre-mRNA occurs.

In addition to the transcribed sequences – called “transcription units” or “units of transcription” – all genes have additional sequences, among them regulatory regions that control their expression. Thus, a common structural organization of a protein-coding eukaryotic gene can be summarized as follows: 5'-enhancer-promoter-exon1-intron1-exon2-...-exonN-termination signal-polyadenylation sequence-downstream regulators-3'. In bacteria and archaea, introns are rare and the average length of genes is shorter. Two extreme examples of gene size are the 21 nt-long gene *mccA*, coding for the heptapeptide antibiotic microcin C7 in *Enterobacteria*, and the 2.3×10^6 nt-long human dystrophin gene, which includes 79 exons and very long introns. The first sequenced gene was that of the bacteriophage MS2 coat protein (Min Jou et al. 1972), an RNA ► **virus** whose genome was also the first to be sequenced in its entirety.

The number of genes in different genomes ranges from 1 in the simplest viruses – viroids lack genes in their genomes – to up to 10^5 in certain eukaryotes. The relationship between genome size and gene content has been investigated based on the data from completely sequenced and annotated genomes. Viral, bacterial, and archaeal genomes are mostly composed of gene-coding sequences, with median values of gene-coding percentages between 85% and 90% in the three groups (range: 47–97%). In turn, in eukaryotes only a small proportion of their genomes is ever transcribed as bona

fide informational RNAs – mRNA, rRNA, or tRNA “true” genes – showing a median gene-coding percentage of about 32% (range: 1–82%). For example, the gene content of the bacterium *Escherichia coli* genome is 88%, whereas in *Homo sapiens* the coding sequences represent less than 2% of our genome (Hou and Lin 2009; Snustad and Simmons 2010).

Gene Expression

Carlos Briones

Centro de Astrobiología (CSIC/INTA), Consejo Superior de Investigaciones Científicas, Madrid, Spain

Definition

Gene expression is the overall process by which information stored in a gene is used to produce a gene product that may be either a protein, including enzymes and structural proteins, or a functional RNA, including ribosomal RNA, transfer RNA, small nuclear RNA, and other non-translated RNAs. Gene expression involves several sequential steps that are highly regulated, such as transcription, splicing, translation, and posttranslational modifications of proteins.

Gene, Selfish

Stéphane Tirard

Centre François Viète d'Histoire des Sciences et des Techniques EA 1161, Faculté des Sciences et des Techniques de Nantes, Nantes, France

Gene selfish is a metaphoric expression coined for the first time in 1976 by the British biologist

Richard Dawkins. Dawkins claimed that gene is the “unit of selection” of the evolutionary process. In his conception, organisms are only systems that permit to genes to reproduce. This idea was central on the debate about the unity of selection that put in opposition Dawkins and S. J. Gould.

Synonyms

[Codon table](#)

Definition

A genetic code defines how genetic information (stored within a polymerized ► [nucleotide](#) sequence) translates into a ► [protein](#) (a polymerized ► [amino acid](#) sequence): specifically it is the set of rules that maps each possible triplet nucleotide subsequence (► [codon](#)) to its corresponding amino acid. For example, the genetic code operating within the human nuclear genome translates the mRNA codon containing uridine-cytidine-

adenosine into the amino acid serine. These rules emerge through base pairing between a codon and the anticodon of an appropriate tRNA (“adaptor molecule”) that was previously charged with a specific amino acid by an appropriate aminoacyl tRNA synthetase enzyme (aaRS).

Overview

The phrase “genetic code” is widely associated with two misunderstandings that obscure its relevance to astrobiology.

First, popular media increasingly use the phrase “genetic code” to refer to the genetic information contained within an organism. However, biologists use genetic code to refer to the system of rules by which organisms translate their genetic information into protein-based metabolism. All known living systems require a genetic code precisely because they partition biochemistry into two different types of polymers – one (nucleic acids) for storing genetic information and another (proteins) for catalyzing the chemical reactions of metabolism. At present, it remains largely unknown whether we should expect an independent origin of life to do likewise. Relevance to the origin, evolution, distribution, and future of life in the universe thus hinges upon understanding how and why genetic coding emerged as a central phenomenon of life on our planet (Freeland 2009).

Second, despite the continuing and widespread use of the phrase “universal genetic code,” no such thing exists. Most known living systems share in common a standard genetic code (Fig. 1a) that maps the 64 possible codons (i.e., each possible triplet combination of nucleotides bearing the bases uracil, thymine, ► [adenine](#), or ► [cytosine](#)) into 1 of 20 amino acid meanings. However, research over the past four decades has revealed numerous non-standard genetic codes at work within naturally occurring genomes (Knight et al. 2001) (e.g., Fig. 1b). Nonstandard codes are widely distributed across diverse evolutionary sub-lineages,

Genetic Code, Fig. 1 Two examples of genetic codes: (a) the standard genetic code at work in most genomes and present within LUCA. (b) An example of a nonstandard genetic code – in this case the one at work within the mitochondria of *Saccharomyces cerevisiae*

and all involve relatively minor changes to the standard genetic code which predominates within all three fundamental domains of life (Archaea, Bacteria, and Eukaryota). It therefore seems likely that the standard genetic code was present within the ► last universal common ancestor (LUCA) of extant life and that all nonstandard codes are subsequent evolutionary diversifications. This shows that while genetic coding is fundamental to biology, it is not fully determined by physics or chemistry: it is an evolved and evolvable phenomenon. Indeed, any genetic code under consideration is usually represented as an exact table of correspondence between individual codons and specific amino acids (e.g., Fig. 1). However, this view is misleading because the process of genetic coding is not exact: it is the outcome of a series of complex molecular interactions; thus a tabulated summary is a statistical approximation. For a codon to be translated into an amino acid, an appropriate tRNA must first be charged with that amino acid by an appropriate aaRS enzyme. In some lineages this amino acid is then modified by further enzymes (e.g., see Wong 2005). The charged tRNA must then compete against others in

order to base-pair with the codon within the molecular context of a ► ribosome (Betney et al. 2010). Errors are inherent to all of these processes, and mismatching an amino acid to a given tRNA species (mischarging) or mismatching an incorrect codon to a correctly charged tRNA species (misreading) causes deviations from the code as written. While mischarging of tRNAs appears comparatively rare (Ling et al. 2009), patterns and frequencies of misreading vary widely between different lineages (Drummond and Wilke 2009). Thus, while the phrase “codon ambiguity” has been coined to describe codons that are routinely translated into more than one amino acid at an unusually high frequency (Moura et al. 2009), a wealth of related research has shown that the fidelity of protein translation depends to a significant (but widely varying) extent on “codon context,” where this is taken to mean the identity of neighboring codons or of RNA motifs located outside of the codon itself (Buckingham 1994). This shows how the precise rules of genetic coding can and do change during evolution, even for such a fundamental and complex feature as the standard genetic code.

Against this background, ongoing research is aimed at understanding better the origin of genetic coding (including the emergence of the standard genetic code), the diversity of genetic codes found within present-day organisms (and how these emerge), and the processes by which biological engineers can manipulate a given genetic code to deviate from anything that occurs naturally (e.g., by incorporating amino acids that have never been part of any naturally occurring genetic code).

Regarding the origin of genetic coding and the emergence of the standard genetic code, an expansive and often speculative literature has converged around three major themes. First, that genetic coding may have originated through direct interactions between ► RNA motifs and the amino acids that they encode (this may also explain the codon assignments of the standard genetic code, though to an unknown extent) (Yarus et al. 2009). Second, it seems likely that the standard genetic code emerged from a simpler genetic code comprising fewer codons and/or fewer amino acids (more than 50 different versions of this broad idea are collated in Trifonov 2000). The most thoroughly developed version, coined “genetic code coevolution,” holds that we can see clues to the order by which amino acids entered genetic coding by comparing the codon assignments of the standard genetic code with conserved metabolic pathways of modern organisms, in which chemically complex amino acids are still formed through biosynthetic manipulation of their simpler amino acid precursors (Wong 2007). An alternative view is that all codons and amino acids were present from the start, but coding was originally highly ambiguous (i.e., groups of codons were translated probabilistically into a meaning drawn from a group of amino acids) (Fitch and Upper 1987). A third major theme is that within the standard genetic code, the distribution of codons to amino acids appears very nonrandom in that amino acids with similar biochemical properties are assigned to codons that differ by only one of their three nucleotides (Freeland et al. 2003). In general, this observation has been used to argue that natural selection shaped the distribution of amino acid meanings to codons so as to

reduce the harmful effects of point mutation. More recently, it has been suggested that the same property may actually enhance the efficiency of natural selection as it acts to adapt protein-coding genes within a changing environment (Zhu and Freeland 2006). These different major lines of research into the origin and emergence of a standard genetic code do not necessarily compete as explanations. In particular, far less attention has been given to the fundamental variables involved: for example, why are codons three nucleotides in length? Why does genetic coding use only four nucleobases and only 20 amino acids of the thousands of examples of each type of compound found in biological systems (see Freeland (2009) for a review of ideas on these topics)? It remains entirely possible, though unknown, whether the standard genetic code emerged as some sort of optimal trade-off involving the steric affinities between mRNA motifs and amino acids, natural selection for an adaptive distribution of codon/amino acid assignments, and the growth of a standard amino acid alphabet from a near-infinite set of possibilities.

Meanwhile, research over the past four decades has uncovered numerous slight variants to the standard genetic code at work within the present-day biosphere (reviewed in Knight et al. 2001). Variations typically involve the reassignment of one or more codons to a different amino acid meaning from that found in the standard genetic code (e.g., within the human mitochondrial genome, the codon AUA corresponds not to isoleucine but to methionine). Many occur within the highly reduced genomes of mitochondria (e.g., eight codons have changed amino acid assignments within the genetic code that operates on the mitochondrial genome of yeast, *Saccharomyces cerevisiae* – Fig. 1b), but others exist within free-living microbes. Nonstandard codes also include examples that use one of two nonstandard amino acids (► selenocysteine and pyrrolysine) (Yuan et al. 2010). Although some maintain that these amino acids are not truly encoded in the same sense as the standard 20, owing to unusual features associated with the process of their translation, this argument fails under careful examination (Freeland 2009). Owing to recent discoveries

of enormous, largely uncharacterized microbial biodiversity (Fierer et al. 2007), it seems likely that current science is far from knowing the full range of nonstandard codes that currently exist within nature. This may well include the presence of additional coded amino acids (although bioinformatics analyses of the world's repositories of protein-coding sequence data suggest that further such discoveries are unlikely to occur within species whose genes have been sequenced so far) (Freeland 2009). Debate still surrounds the mechanisms by which codons become reassigned to new amino acid meanings (e.g., see Sengupta et al. 2007), but a large quantity of empirical data shows that mistakes routinely occur in the process by which tRNAs bond with their cognate codons. In some cases, this mismatching reaches levels at which a codon is declared “ambiguous” with respect to its amino acid meaning (e.g., Moura et al. 2009). More generally, evidence is growing that many features of an mRNA sequence can influence the accuracy with which a codon is translated. As an evolutionary route to codon reassignment, this is consistent with the finding that the two nonstandard amino acids to have been incorporated into coding are typically associated with mRNA motifs that lie outside of the codon itself (reviewed in Yuan et al. 2010).

More recently, researchers have begun to demonstrate success in manipulating the rules of genetic coding within the laboratory. In particular, the emerging science of synthetic biology has successfully incorporated additional amino acids into the standard genetic code within model organisms (Xie and Schultz 2006). Given the recent origin of this research, its rapid success, and the inherent economic and biomedical potential, significant future progress seems likely. In particular, scientists elsewhere have successfully incorporated additional bases into DNA (e.g., see Geyer et al. 2003). This offers the potential for a combination of the two technologies to greatly enlarge the complexity of the genetic code, producing proteins that have no analogs within nature, without disrupting current genomes and their translation into metabolism.

[Linkage map](#)

Definition

A genetic map is a representation of the genes on a linear map on which the distances are expressed as frequency of crossing-over or percent ► [recombination](#). Genetic distance in the map has no physical units: Its unit – m.u or centiMorgan – corresponds to 1% of recombination. Genetic distance describes the tendency of two given genes on the same chromosome to be inherited together: If they are physically close to each other, they will tend to stay together withstanding the recombination events produced during meiosis, a form of cell division in eukaryotes essential for sexual reproduction. In turn, genes far away from one another will have a long genetic distance since they show a higher probability to be separated as a result of recombination. Thus, the physical proximity on a same chromosome explains the correlation with the degree of genetic linkage evidenced in the crossing experiments. Overall, a ► [genome](#) has as many linkage groups as chromosomes. For example, humans have 24 linkage groups: the 22 autosomes – chromosomes that contain genetic information available to both sexes – plus the sex chromosomes X and Y. Gene mapping has important applications, including the production of the first drafts during a genome sequencing project.

Definition

Genetics is the discipline of Biology which studies inheritance, variation, function, and the physical nature of the genetic material. Historically, genetics has proceeded along several major pathways including experimental breeding, pedigree analysis, population genetics, cytogenetics, molecular genetics, and genetic engineering. Among them, molecular genetics is mainly concerned with the molecular bases of the inheritance and variation of the ► [genotypes](#) and investigates the relationship between the information-bearing macromolecules – DNA and RNA – and the proteins encoded by them. Applied branches of genetics rely on the established genetic principles and are used in medicine, agriculture, and biotechnology.

Overview

Early naturalists essentially observed the heritable traits of animals or plants in an empirical manner,

based on a long tradition of experimental breeding dating back several centuries. This approach was followed by pedigree analysis, by which the inheritance of some specific traits was traced in all members of a family line. For example, human pedigrees traced the inheritance of certain diseases such as polydactylism, hemophilia, or albinism. G. J. Mendel, considered the father of genetics, described in 1866 the basis of inheritance of traits from one generation to the next. At the beginning of the twentieth century, after the rediscovery of Mendel's work and following an increasing interest in cytology and biochemistry, the term “genetics” was coined in 1905 by W. Bateson to describe the study of heredity and variation (Bateson [1907](#)). The field of population genetics came into being in the 1920s to study the distribution of ► [genes](#) in biological populations and their change under the influence of evolutionary processes. It was based on the synthesis of the principles of Mendelian genetics with Darwinian natural selection (Sturtevant [2001](#)).

The observation that DNA is the genetic material in all ► [cells](#) and the discovery of the structure of DNA as a double helix inaugurated the era of molecular genetics in the decade of the 1950s. The investigation within this field has shown that all cells and a fraction of ► [virus](#) families have DNA genomes, while RNA is the genetic material of other viruses and all ► [viroids](#). The overall flow of genetic information in cells and viruses can be represented as $\text{DNA} \leftrightarrow \text{RNA} \rightarrow \text{Proteins}$, as schematized in Fig. 1. The spectacular progress produced in molecular biology opened the possibility to introduce tailored modifications in the genetic material of organisms, which gave rise to genetic engineering in the 1970s (Alberts et al. [2002](#); Lewin [2008](#)).

Since 1990, the advances in DNA sequencing and bioinformatics opened the possibility to study whole genomes of organisms as well as their set of encoded products, thus initiating the current era of genomics and proteomics. The publication of the first draft of the human ► [genome](#) in 2001 and its relevance for modern medicine has expanded broadly the subfield of human molecular genetics (Strachan and Read [2004](#); Watson et al. [2008](#)). In turn, recent advances in biotechnology allowed

Genetics,

Fig. 1 Schematic representation of the flow of genetic information. Cellular processes are shown by *solid arrows*, while those found only in viruses are depicted as *dotted arrows*

the study of the ► “**metagenome**” of communities containing different species (e.g., Venter et al. 2004), as well as the analysis of genetic material from extinct organisms, in the interdisciplinary field of paleogenetics (e.g., Poinar et al. 2006).

In summary, the tools and developments of genetics are currently integrated into all biological disciplines, including origin and evolution of life, taxonomy, microbiology, virology, molecular biology, biochemistry, biophysics, biotechnology, cytology, physiology, and development. Additionally, advances in genetics have permeated other fields such as medicine, forensics, psychology, sociology, paleontology, and astrobiology.

History

It is quite impossible to pinpoint the origin of ► [genetics](#). The resemblances, but also the differences, between children and their parents (or grandparents), as well as the experience of breeders with animals, represent common ancestral knowledge. The evidence that characteristics, but also potentialities, were transmitted from one generation to the next was widely accepted. These spontaneous “prescientific” observations coexisted with the theory of impregnation, the conviction that characteristics acquired during life could be transmitted, and the idea that the thoughts and imagination of the mother might imprint their shapes on the future newborn. These empirical observations did not constitute a science of heredity, the systematic study of the transmission of characters through generations. The father of the science of heredity is Gregor J. Mendel, who in the garden of the monastery of Brno discovered the so-called laws of heredity. The work of Mendel was ignored by his contemporaries (including Charles R. Darwin), but was rediscovered 35 years later, on the eve of the twentieth century, by Hugo de Vries, Carl Correns, and Erich von Tschermak.

Mendel is the emblematic example of a “precursor,” a man or woman who anticipates the future progress of knowledge. Historians have done much to dispel the legend surrounding Mendel and his discovery. He was not a monk isolated in his monastery, but a recognized scientist, in contact with other scientists of his time, and well aware of the most recent scientific developments. His project was not the establishment of the laws of heredity, but the search for an answer to a practical question faced by all gardeners and breeders: why are some hybrids stable and others unstable? And when the hybrids are not stable, how do they return to the parental types? He had the merit to look for (and discover) quantitative laws of transmission of characters. But he had no clear idea of “what” transmitted these characters from one generation to another.

The 35 years which separated Mendel from the rediscovery of his laws was necessary to convince biologists of the existence and importance of the mechanisms of heredity. In 1859, simultaneously but independently of Mendel’s work, Darwin proposed his theory of evolution, which called for the existence of a mechanism of transmission through generations of the spontaneous variations screened by ► [natural selection](#). Ten years later, Darwin proposed his model of pangenesis. This model was neither original nor based on experimental evidence. But it triggered the work of many biologists, including August Weismann and Hugo de Vries, who proposed alternative models of heredity. In parallel and in relation with cytological observations on the nucleus, the chromosomes, and the mechanisms of fertilization, these authors elaborated what the historian of biology Garland E. Allen has described as corpuscular and mechanistic models of heredity (Allen 2000). Minds are now ripe for the rediscovery of Mendel’s laws.

The first 10 years of the science of genetics (1900–1910) was necessary to separate characters from genes or, as Wilhelm Johannsen said, ► [phenotype](#) from ► [genotype](#) and to propose that the chromosomes were the bearers of the genes (a hypothesis made by W. S. Sutton and Th. Boveri in 1902). A brilliant confirmation of

this hypothesis and the choice of an appropriate experimental system (the fruit fly *Drosophila melanogaster*) were due to Thomas H. Morgan and his small group of collaborators working at Columbia University in New York (Allen 1978). Sturtevant and Morgan rapidly demonstrated that the genes present on the same chromosomes were not always transmitted together. They interpreted this observation thanks to the 1909 discovery by the Belgian cytologist R. A. Janssens of the recombination of the chromosomes during meiosis (the cell division mechanism by which germ cells eliminate half of their chromosomes). This explanation allowed the drawing of genetic maps: the probability of genes being separated by chromosome breaks is proportional to the physical distance separating these genes on the chromosome.

Rapid progress was made in genetics, not only with *Drosophila* but also with maize and humans. Despite this intense effort of genetic mapping, the questions of the nature of the ► [gene](#) and of the mechanisms by which genes were responsible for the formation of characters not only were not addressed but were ignored. In his Nobel lecture (1934), Morgan still stated that defining the nature (material or not) of the genes would not alter the research program of geneticists.

Geneticists' apparent lack of interest in the nature and mechanism of action of genes probably has its roots in the empiricist philosophical tradition which permeated the minds of many scientists and biologists at the beginning of the twentieth century. Establishing the laws by which characters were transmitted through generations, and ignoring the mechanisms by which they were reproduced at each generation, was also a strategy to maintain the separation between genetics and embryology and the autonomy of the former. Indeed, the nature of genes and the mechanisms by which genes control the formation of characters were difficult scientific questions, experimental approaches to which were still lacking.

This abstract nature of the gene did not prevent the wedding between genetics and Darwinism which occurred in the 1930s through the work of

John Haldane, Sewall Wright, and Ronald A. Fisher. They elaborated the sophisticated mathematical models of population genetics, which provided a precise definition of ► [fitness](#), and demonstrated that mutations of small amplitude and low selective pressures were sufficient to drive the transformation of organisms. The modern synthesis, the new theory of evolution, emerged in the 1940s from the transfer of genetic studies done in the laboratory to fieldwork (Theodosius Dobzhansky), from an elaboration of complex mechanisms of speciation (Ernst Mayr), and from an interpretation of paleontological data in the light of the models of population genetics (George Simpson).

Meanwhile, the abstract notion of the gene was progressively replaced by a pure chemical description. In the 1930s, cytochemical studies demonstrated that ► [DNA](#) and proteins were the main constituents of chromosomes. In 1944, Oswald Avery and his collaborators produced strong arguments in favor of a major role of DNA in the process of heredity. The double-helix model proposed by Jim Watson and Francis Crick paved the way to the explanation of how the DNA molecule was faithfully replicated and suggested that the order of bases in DNA was probably the basis of genetic information. At the beginning of the 1960s, the genetic code was deciphered, demonstrating how the nucleotide ► [sequence](#) of DNA controlled the order of amino acids in proteins and therefore their structures. Genes had been reduced to DNA. The identification of the gene with an object seemed complete.

But the situation rapidly deteriorated. The discovery of regulatory sequences, located upstream of the coding regions of the genes, initiated a process of structural deconstruction of the gene. These sequences cannot belong to the gene, since they can be shared by different genes. Nevertheless, they are necessary for the proper activity (expression) of the gene. Other difficulties emerged: the existence of split genes in eukaryotes, the capacity for a DNA sequence to generate different messenger RNAs and proteins, the editing process, and the existence of DNA sequences coding in different frames for

totally distinct proteins. These were some of the observations preventing a simple definition of the gene.

The same difficulties also emerged at the functional level. Initially, it was admitted that a gene coded for an enzyme, a ► [protein](#) with a well-determined chemical function. Other protein functions were progressively discovered: ligand receptors, transcription factors, adaptors, etc. These new functions only find their meaning at a more integrated level, by conjunction with other proteins. Many genes participate in the formation of one single character. This was not a real surprise for geneticists, but it found its explanation in the progressive description of these molecular actors. In most cases, the expression “gene for” has no meaning!

The present situation is not simple, and efforts to provide a general definition of a gene have failed. Is the solution to be found in the replacement of the single notion of gene by different well-defined concepts (Keller 2000)? Many have argued for this and have even proposed these new concepts. But the notion of gene is still alive and well. Its vagueness allows this “boundary object” to circulate between different disciplines and to fertilize each of them.

Definition

The genome is the total amount of the genetic information of a ► [species](#). It can also be defined as the basic haploid chromosome set of a species. The term “genome” has also been used to refer to the full hereditary information of an organism. Nevertheless, the term ► [“genotype”](#) is preferred for individual organisms, since the “genome” of a given species is in practice an average or consensus of the genetic information of a number of individuals belonging to that species. Thus, the genome of one species does not capture the genetic polymorphisms within it.

Overview

All cellular genomes are composed of double-stranded (ds) ► [DNA](#), while viruses can have DNA or ► [RNA](#) genomes as both single-stranded

(ss) and ds molecules. In turn, all ► **viroids** show ssRNA genomes. Genomes can have linear or circular topologies, and they are composed of either a single DNA or RNA molecule or a set of different ones, each of them carrying a fragment of the whole genetic information. Genome sizes vary from less than 300 nucleotides (nt) in the smallest viroids to up to 10^{11} base pairs (bp) in certain vertebrate animals and higher plants. Some species have haploid genomes with a single copy of their genetic information, while others harbor multiple copies of the information in their

diploid, triploid, or polyploid genomes (Lewin 2008; Gibson and Muse 2009).

Cellular genomes show one or more ► **chromosomes** – molecules of dsDNA with a certain degree of structural organization – together with, in most microorganisms, extrachromosomal elements such as ► **plasmids**, viruses, or transposons. In eukaryotes, apart from the chromosomes composing their nuclear genome, two organelles – mitochondria and chloroplasts – harbor dsDNA genomes contributing to the overall genome of the species. Genomes contain both the coding

Genome, Table 1 Sequenced genomes from representative viroids, viruses, and cellular organisms from the three domains of life

^aFirst complete genome sequenced within each group

^bDefective virus

^cSegmented viral genome

► **genes** – nucleic acid sequences that will be translated into proteins – and the noncoding genetic information. The latter includes the rRNA, tRNA, and other small RNA genes, as well as different kinds of regulatory sequences, structural elements, and sequences whose function is at present unknown. Comparative genomic methods have been widely used to identify genes and regulatory regions in different species, as well as to trace patterns of genome evolution (Gibson and Muse 2009; Nielsen et al. 2010).

Genome projects are aimed at determining the sequence of the entire genome of one species. Upon completion of a sequencing project, the physical or ► **genetic map** of the genome and the inventory of annotated genes and regulatory regions become available. The first complete genome sequenced belonged to an RNA virus, the bacteriophage MS2 (Fiers et al. 1976), followed by the DNA genome of the bacteriophage PhiX174 (Sanger et al. 1977). Since then, thousands of complete viral and cellular genomes have been already sequenced or are in progress. Table 1 shows representative examples of sequenced genomes. The sequencing projects of long and complex genomes, such as those from higher plants and animals, require years of joint experimental and bioinformatic work. Among them, the Human Genome Project produced the first draft of the complete genome of our species in 2001 (Lander et al. 2001; Venter et al. 2001). This achievement was followed by a rapid acceleration in genome science and ► **DNA sequencing** techniques, what has opened the door to a future genome-based, personalized medicine (Collins 2010). Apart from their applications in biomedicine and biotechnology, the advances in genomics have largely influenced our current view of different disciplines of biology (Snustad and Simmons 2010).

Definition

Genome editing stands for the capacity to modify and manipulate a genome at will, using specific tools triggering specific alterations in selected DNA sequences at target genome sites. The first experimental observations of genome editing events were reported in yeast cells. Subsequently, homologous recombination strategies were implemented in higher eukaryotes as part of the gene targeting approaches in mice using embryonic stems cells. Genome editing tools that have been developed include yeast meganucleases, Zinc-Finger nucleases (ZFN), transcription activator-like effector nucleases (TALEN), and clustered regularly interspaced short palindromic repeats (CRISPR), and CRISPR associated proteins (Cas) systems.

History

Genome (or gene) editing was first reported in yeast cells (*Saccharomyces cerevisiae*) in 1979, with specific genome alterations generated by homologous recombination. Oliver Smithies used homologous recombination to target a mammalian gene in 1985, and this approach was combined with the isolation of mouse embryonic stem cells by Martin Evans in 1981 into a general strategy to target specific genes in mice by Mario Capecchi in 1988. Subsequently, specific tools were developed to trigger genome editing events. First using yeast meganucleases, in 1995. Then combining artificial ZF domains with nucleases, for ZFN, since 2001. Thereafter, TALEN come into play in 2010, although they were rapidly replaced by the nascent CRISPR-Cas technology, envisaged in 2012 and demonstrated from 2013.

Overview

The ability to modify a genome at will was first demonstrated in yeast cells, using a homologous

recombination approach, activating the homology drive repair (HDR) endogenous mechanism. Thereafter, a most similar strategy was confirmed in mammalian cells by Smithies and converted to a general approach to edit mouse genes at will. The three researchers involved in this seminal innovation: Smithies, Evans, and Capecchi, were awarded the Nobel Prize in Medicine in 2007. The fact that genome editing events were triggered by specific double-strand breaks at the target DNA sequence and the observation that the subsequent chromosomal repair could progress through HDR, in the presence of DNA homologous sequences, or through NHEJ (non-homologous end joining), in their absence, was further explored with several types of endonucleases. At first, using yeast meganucleases, capable of detecting and cutting long target DNA sequences (20–40 base pairs) but with limited versatility. Next, a combination of artificial ZF domains targeting specific DNA sequences with a prokaryotic nuclease domain from restriction enzyme *FokI* created the ZFN, first tested in 2001, thus expanding the target genomic sites to any desired DNA sequence. However, ZFNs were difficult to generate, and their fabrication was proprietary of a company. In contrast, the TALE nucleases, in place since 2010 and derived from bacteria infecting plants, could be generated at any laboratory, although with significant efforts, and transiently resulted in the preferred choices for triggering genome editing. Eventually, the proposal of CRISPR-Cas systems as easier, cheaper, more efficient, and most amenable genome editing tools, presented by Charpentier and Doudna in 2012, disrupted the entire field. The two reports by Zhang and Church in January 2013 confirmed these would be the future reagents of choice for effective genome editing experiments.

Definition

A minimal genome was defined in 1999 by Arcady Mushegian as a genome containing the smallest number of genetic elements sufficient to build a modern-type free-living cellular organism (Mushegian 1999). Consequently, the concept of a minimal genome is fundamentally related to the definition of a minimal cell.

Overview

The functional elements of a living cell are (lipid) membranes, proteins, and RNA molecules. The instructions for making these parts are encrypted in genes (i.e., DNA) and decoded by the molecular cell machinery in a controlled manner. In order to delineate a set of essential and sufficient genes to make a living cell, it is first necessary to define the essential functions that need to be achieved. Most attempts to define a minimal genome focus on protein-coding genes, ignoring functional

RNAs, regulatory and other noncoding sequences, and the organization of these elements on chromosomes. Therefore, they only represent the core of a hypothetical minimal modern-cell genome. Several estimates indicate that such minimal genome core must contain at least about 200 genes, although some authors point out that additional genes might be necessary to improve cell efficiency (Fang et al. 2015; Jewett and Forster 2010).

It is not possible to specify a universal minimal genome. First, it needs to be tied to a particular level of biological organization. The increasing knowledge on bacterial genomes and the simplicity of prokaryotic cells make bacterial cells a suitable choice. Second, metabolism is extremely variable and highly dependent on the environment. Therefore, a plethora of minimal genomes, composed by a universal informational core plus a variable metabolic gene-set, can be envisaged (Gil et al. 2004; Gil and Peretó 2015).

Experimental and computational methods have been used to define the core of a minimal bacterial genome (Gil 2015). Experimentally, essential genes are determined based on indirect evidence from systematic and genome-wide inactivation or inhibition of each individual gene present in a genome (compiled in <http://origin.tubic.org/deg>; Luo et al. 2021). Computational comparative genomics has been also extensively employed, assuming that genes shared between distant organisms are likely to be essential. Naturally reduced genomes from bacteria with a host-associated lifestyle have been used for comparisons because they must be closer to a minimal genome (Gil et al. 2003; Mushegian and Koonin 1996). These studies showed the importance of considering that essential functions can be performed by alternative and unrelated (non-orthologous) proteins. Comparative analyses only retrieve genes involved in functions for which there is no alternative in nature (e.g., the complex translational machinery), while a minimal genome must also include all genes essential to maintain metabolic homeostasis (Gil et al. 2004).

A third approach to a minimal genome searches for the biochemical and modular description of well-defined pathways needed to perform all essential functions (Jewett and Forster 2010). Although some important challenges still need to be faced, this approach allows a function-by-function debugging to reach self-replication, and it seems a good start to approach the goal of synthesizing a minimal genome able to sustain an artificial minimal cell, the ultimate goal of synthetic biology.

The possibility of chemically synthesizing complete genomes and transplanting them into pre-existing cells has revolutionized the study of minimal genomes (Hutchison et al. 2016). With only 543 kbp and 493 protein-coding genes, the *Mycoplasma mycoides* JCVI-syn3A genome is close to a minimal one and has proven to be able to sustain a robust free-living near-minimal cell. It includes essential and quasi-essential genes, some of which (79 genes) have poorly defined functions, and later studies indicate that it can still be reduced (Breuer et al. 2019). The design of a truly minimal genome can also benefit from computational whole-genome sequence rewriting and a design-built-test in silico approach prior to the chemical synthesis of a customized genome (Venetz et al. 2019; Zhang et al. 2020, 2021).

Genomics

Carlos Briones

Centro de Astrobiología (CSIC/INTA), Consejo Superior de Investigaciones Científicas, Madrid, Spain

Definition

Genomics is the field of ► [genetics](#) which studies the structure, organization, and function of entire genomes. This global and integrative approach was initiated in the decade of the 1980s, thanks to the advances in automatic ► [DNA sequencing](#) and the availability of new bioinformatic tools for analyzing increasingly large amounts of genetic information. Four milestones in genomics were the sequencing of the first viral genome in 1976, the completion of the first bacterial genome in 1995, the first eukaryotic genome in 1996, and the release of the first draft of the human genome in 2001. Different current subfields of genomics include structural genomics, functional genomics, metagenomics, pharmacogenomics, and comparative genomics.

Genotype

Susanna Manrubia
Systems Biology Program, Centro Nacional de
Biotecnología (CSIC), Madrid, Spain

Definition

The genotype is the genetic makeup of an organism, its full hereditary information. The genotype of an organism is a characteristic fingerprint. Genotype is different from ► [genome](#) (usually describing a species), which is a representative average over individuals. For example, a viral ► [quasispecies](#) contains a particularly large number of different genotypes, though the ► [virus](#) is characterized by a precise genome. In diploid organisms, the genotype is the pair of alleles inherited for each particular gene. The expression of the genotype in a given environment is the ► [phenotype](#) of an organism.

Genus

Ricardo Amils
Departamento de Biología Molecular,
Universidad Autónoma de Madrid, Madrid, Spain

Definition

Genus is a taxonomic group of related ► [species](#) sharing one or more major properties. The term comes from the Latin genus meaning “descent,

family, type, and gender,” cognate with Greek: γένος-*genos*, “race, stock, and kin.” A genus is defined through the characterization of different species. In order for a genus to be descriptively useful, it must have monophyly, reasonable compactness, and distinctness. In the binomial nomenclature used in biology, the genus is used as the first word of a scientific name. The genus name is always capitalized and italicized. In the hierarchy of the binomial classification system, genus comes above species and below family. In the past, the taxonomic adscription of organisms was based on phenotypic properties, but since the introduction of molecular biology, techniques allowing the use of genotypic properties have facilitated the establishment of phylogenetic relationships among organisms.

Geobiology Society

Kurt O. Konhauser
Department of Earth and Atmospheric Sciences,
University of Alberta, Edmonton, AB, Canada

Definition

The Geobiology Society is a nonprofit international society formed in 2016 to advance the science of geobiology. Its aims are to foster collaboration and the exchange of ideas between geobiologists worldwide; promote the study of geobiology as a core Earth and life science discipline for the twenty-first century; enhance scientific communication by means of publications, lectures, meetings, and collaboration with other relevant societies; support and encourage young

scientists entering the field of geobiology; encourage the development and use of new analytical techniques; and promote the relevance of geobiology to society at large.

Geocentric Worldview

Sun Kwok

Department of Earth, Ocean, and Atmospheric Sciences, University of British Columbia, Vancouver, BC, Canada

Keywords

Ptolemy · Epicycles · Eccentric · Equant · Two-sphere universe

Definition

A cosmological worldview where the Earth is located at the center of the Universe.

History

Because the ground is apparently flat, and the Sun, the Moon, and the stars rise from one horizon, move across the sky in circular paths, and set in the opposite horizon, many cultures developed the flat Earth-spherical sky model as their first cosmological model. However, this model has difficulty accounting for the fact why some stars (e.g., Canopus) are visible from some locations (e.g., Alexandria), but not from others (e.g., Athens). From the shape of the shadow of the Earth during lunar eclipses, Greek astronomers deduced that the Earth is round in the fifth century B.C. A spherical Earth means that observers at different latitudes will have different horizons, and thus explains the trajectory of the Sun and the visibility of stars are dependent on observer's location.

Overview

The realization that the Earth is round led to the two-sphere universe model where a spherical

Earth is situated at the center of a celestial sphere upon whose surface the stars lie. In this model, the celestial sphere revolves around the Earth from east to west each day. Because of the rotation of the celestial sphere, stars rise above the horizon in the east and set below the horizon in the west. The Sun also revolves around the Earth, but its motion is slower than that of the stars by 4 minutes each day. Over the course of a year, the Sun travels across the celestial sphere relative to the stars from west to east along the plane of the ecliptic, which is inclined 23.5° with respect to the equator of the spherical Earth. Because of this inclination angle, the Sun goes through a north-south annual motion in addition to its daily east-west motion. This model explains the cause of the seasons, and quantitatively predicts the daily changing positions and times of sunrise/sunset. Most significantly, it can predict the trajectories of the Sun as observed from anywhere on Earth, even from places that no one has visited (e.g., the north pole).

While the two-sphere universe model achieved great success in explaining the movement of celestial objects, there are other complications. Although the seasons return in regular annual intervals, the lengths of each season are unequal. This anomaly was known as early as 330 B.C. by Callippus (370–330 B.C.), and the different lengths of the seasons were accurately measured by Hipparchus (185–120 B.C.). Although the planets generally revolve around the Earth from west to east, as does the Sun, they appear to reverse directions (retrograde motion) from time to time. Hipparchus also found that the sphere of fixed stars is not oriented permanently with respect to the ecliptic. The intersection point between the celestial equator and the ecliptic shifts about 1° every 100 years; a phenomenon known as the precession of the equinox.

To explain these anomalies, Ptolemy in the first century A.D. introduced additional elements into the two-sphere universe model. Epicycles (cycles upon cycles) were introduced to explain the retrograde motions of the planets. A planet moves uniformly around an epicycle whose center

Geocentric Worldview,

Fig. 1 The use of eccentric, epicycle, and equant in Ptolemy's model of planetary motion. The Earth and the equant are placed at equal distances on opposite sides of the center of the deferent. The planet moves uniformly around the center of the epicycle which revolves around the deferent centered on a point eccentric from the Earth. The angular speed of the center of the epicycle is uniformly relative to the equant point

revolves along a large circle called the deferent. When the planet is in the inside of the deferent, it is in retrograde motion (Fig. 1).

The concepts of eccentric and equant were also needed to explain the unequal lengths of the seasons, the uneven motion of the planets, and the precession of the equinox. The center of the deferent is separated from the position of the Earth by the eccentric. The center of the epicycle revolves uniformly relative to the equant.

Ptolemy's model was described in detail in his book *Almagest*. Planetary tables produced from his model were used to predict future solar and lunar eclipses, and planetary conjunctions. It was the dominant cosmological model for over 1400 years. In the thirteenth century, St. Thomas Aquinas integrated Ptolemy's model with Aristotle's physical worldview and the Bible to form a comprehensive geocentric cosmology. Earth is centrally located with Hell in its center, and Heaven is located beyond the celestial sphere.

In this picture, humans are special and unique, and there are no other living worlds. This geocentric worldview was finally challenged by the heliocentric model of Copernicus (1473–1543).

Geochronology

Francis Albarède

Laboratoire de Géologie de Lyon, Ecole Normale Supérieure de Lyon, Lyon Cedex 7, France

Keywords

Age · Absolute age · Ion microprobe · Isochron · Isotope · Radioactivity · Radioactive decay · Mass spectrometer · Extinct radioactivity

Synonyms

[Age measurement](#); [Radiochronology](#)

Definition

Geochronology is the scientific field dedicated to providing absolute ages of geological and planetary material. It is based on the measure of the accumulated isotopes produced by the ► [radioactivity](#) of some long-lived ► [nuclides](#). The radioactivity of now extinct nuclides can be used to date the early evolution of the solar system. Most of the techniques involved in this field are based on ► [mass spectrometry](#).

History

French physicist Henri Becquerel discovered radioactivity in 1896, and, at the turn of the century, Marie and Pierre Curie successfully separated several radioactive elements. The idea of dating rocks by using the rate of accumulation of helium produced by the decay of uranium was conceived by English physicist Sir Ernest Rutherford in 1904. In the early part of the twentieth century, J. J. Thompson, A. J. Dempster, and F. W. Aston developed the first mass spectrometers. Subsequently A. O. Nier built an instrument that could be used to determine precise isotopic ratios. He is also

credited for the determination of the isotope compositions of most elements in the 1930s and 1940s. Between 1920 and 1953, significant advances in the understanding of the potential of Pb isotopes for chronology are due to A. Holmes, H. N. Russell, F. G. Houtermans, and E. Gerling. In 1955, C. C. Patterson obtained the first Pb-Pb ► [isochron](#) age on meteorites and dated the solar system at 4.55 Ga, a number that has hardly changed today. G. W. Wetherill should be credited for the introduction of the Concordia in 1956 and, together with T. Aldrich, for pioneering the ^{40}K – ^{40}Ar and the ^{87}Rb – ^{87}Sr methods. The merit of discovering extinct radioactivities falls on J. H. Reynolds in 1960 for ^{129}I – ^{129}Xe and on T. Lee and D. A. Papanastassiou in 1974 for ^{26}Al – ^{26}Mg . In 1961, L. Nicolaysen proposed the first isochron for the ^{87}Rb – ^{87}Sr pair. R. Castaing and G. Slodzian constructed the first effective ion probe in the early 1960s and in the late 1970s, which opened the way to the in situ U-Pb ages of zircons, developed then by W. Compston. C. Merrihue and G. Turner invented the ^{39}Ar – ^{40}Ar method in 1965. In 1969, D. A. Papanastassiou and G. W. Wasserburg constructed the first computer-assisted mass spectrometer, which established the post-Apollo standard for isotope geochemistry. The first ICP-source mass spectrometers dedicated to isotopic measurements and geochronology appeared in the mid-1990s.

Overview

Radioactive decay is a random process that reflects the instability of some nuclei. Its probability of occurrence per unit of time is independent of time: atoms do not age. This probability, also known as the decay constant λ , is specific to each radioactive nuclide. A parameter related to the decay constant is the ► [half-life](#) $T_{1/2}$, which is equal to $\ln 2/\lambda$. Radioactive decay is described as a random “Poisson” process, in which the number of events is proportional to the duration of the

observation. In the absence of any other loss or gain (the closed-system assumption), the proportion of parent atoms P (or radioactive nuclides) disappearing per unit of time t is constant:

$$\frac{dP}{Pdt} = -\lambda \quad (1)$$

The number of decay events per unit time dP/dt is known as the “activity” of the radioactive nuclide. For a number of parent atoms $P = P_0$ at time $t = 0$, this differential equation is equivalent to

$$P = P_0 e^{\lambda t} \quad (2)$$

To determine the age of a system from the measurement of the number of parent atoms at the present time, we must know P_0 , and therefore, in this form, this equation is not a chronometer (a notable exception is the ^{14}C method). For each parent atom, a daughter atom (or radiogenic nuclide) is created, usually of a single element, whose number can be denoted D . In a closed system and for a stable daughter nuclide D , the number of parent and daughter atoms is constant; hence,

$$D = D_0 + P_0 - P = D_0 + P(e^{\lambda t} - 1) \quad (3)$$

The term $P(e^{\lambda t} - 1)$ is a measure of the accumulation of the radiogenic nuclide during time t , and therefore,

$$t = \frac{1}{\lambda} \ln \left(1 + \frac{D - D_0}{P} \right) \quad (4)$$

Even if D and P are measured, this equation is no more a timing device than Eq. (2) unless we know the number of daughter atoms D_0 at time $t = 0$.

“Rich” Chronometers: U-Pb and K-Ar

A first class of chronometers arises when the condition $D_0 \ll D$ or

$$D \approx P(e^{\lambda t} - 1) \quad (5)$$

applies, as for the ^{206}Pb – ^{238}U dating of zircons, a ubiquitous mineral of granites with formula ZrSiO_4 into which U^{4+} easily substitutes but not Pb^{2+} . With this condition applying, Eq. (4) becomes

$$t = \frac{1}{\lambda_{238\text{U}}} \ln \left(1 + \frac{^{206}\text{Pb}}{^{238}\text{U}} \right) \quad (6)$$

When $y = ^{206}\text{Pb}/^{238}\text{U}$ and $x = ^{207}\text{Pb}/^{235}\text{U}$ are plotted against each other, the widely used concordia diagram is obtained (Fig. 1). The Concordia is the locus of points for which the two ages of zircons agree, i.e., they are concordant:

$$x = \frac{^{207}\text{Pb}^*}{^{235}\text{U}} = e^{\lambda_{235\text{U}} T} - 1 \quad (7a)$$

$$y = \frac{^{206}\text{Pb}^*}{^{238}\text{U}} = e^{\lambda_{238\text{U}} T} - 1 \quad (7b)$$

where T stands for the geological age and the asterisk refers to radiogenic Pb (total Pb minus common or contamination Pb). The main limitation of this method is the presence of common Pb introduced by inclusions, impurities, or contamination during mineral processing.

The ^{40}K – ^{40}Ar method also belongs to this family and dates the isolation of the host mineral. These days, it is mostly used in its ^{39}Ar – ^{40}Ar version, that is, after irradiation of the sample in a nuclear reactor, fast neutrons with an energy >1 MeV react with ^{39}K , which is in constant proportions with ^{40}K , to produce ^{39}Ar . The age is deduced from the $^{40}\text{Ar}/^{39}\text{Ar}$ ratio, in lieu of $^{40}\text{Ar}/^{40}\text{K}$, after proper calibration of the yield of the nuclear reaction through a mineral standard of known ^{40}K – ^{40}Ar age T_m referred to as the monitor:

$$\frac{\left(^{40}\text{Ar}/^{39}\text{Ar} \right)_{\text{spl}}}{\left(^{40}\text{Ar}/^{39}\text{Ar} \right)_{\text{m}}} = \frac{e^{\lambda_{40\text{K}} T_{\text{spl}}} - 1}{e^{\lambda_{40\text{K}} T_m} - 1} \quad (8)$$

Geochronology, Fig. 1 The concordia plot, with U and Pb analyses of two detrital zircon grains from the Jack Hills (Western Australia) by Wilde et al. (2001). The concordia is the locus of points for which the ^{206}Pb – ^{238}U and

^{207}Pb – ^{235}U ages (here shown in Ga) agree. When zircons plot significantly off the concordia, the age used in practice is deduced from the upper intercept with the line going through the origin ($^{207}\text{Pb}^*/^{206}\text{Pb}^*$ age, dashed lines)

A major advantage of this technique is that resetting of the chronometer by thermal reheating or weathering and the presence of excess Ar can be easily identified. Argon is released by laser ablation or, most commonly, by stepwise heating: undisturbed minerals show very large “plateaus” with $^{40}\text{Ar}/^{39}\text{Ar}$ remaining constant over a broad range of ^{39}Ar degassing, whereas, for perturbed samples, $^{40}\text{Ar}/^{39}\text{Ar}$ reflects old ages only for high-temperature steps. In the case of inherited Ar, the high-temperature steps may be anomalous. Figure 2 shows a ^{39}Ar – ^{40}Ar dating of the famous Martian meteorite ALH84001 (Bogard and Garrison 1999), which has been suggested to harbor microfossils. A limitation of this technique is the presence of atmospheric ^{40}Ar , which is corrected for by measuring ^{36}Ar and using $(^{40}\text{Ar}/^{40}\text{Ar})_{\text{atm}} = 295.5$. Argon loss also happens easily, because it is a rare gas with no ionic or covalent bonding in crystals: only the weak van der Waals forces bind Ar to other species.

“Poor” Chronometers: Isochrons

For a second class of chronometers, the condition $D_0 \ll D$ does not apply, and we replace it by the principle of isotopic homogenization. Isotope fractionation (both natural and analytical) is simply corrected for by internal normalization against some arbitrary reference ratio of stable isotopes, for example, $^{179}\text{Hf}/^{177}\text{Hf} = 0.7325$ for Hf. In marine carbonates, the $^{87}\text{Sr}/^{86}\text{Sr}$ ratio is exactly the same in calcite as in the seawater from which it precipitated; as the mantle melts, $^{176}\text{Hf}/^{177}\text{Hf}$ is the same in the molten liquid as in the residue. Let us therefore divide Eq. (3) by the number D' of atoms of a stable isotope of the same element as the radioactive nuclide represented by D . Because the system is closed, D' remains constant, and therefore,

$$\left(\frac{D}{D'}\right)_t = \left(\frac{D}{D'}\right)_0 + \left(\frac{P}{D'}\right)_t (e^{\lambda t} - 1) \quad (9)$$

Geochronology, Fig. 2 ^{39}Ar – ^{40}Ar in the gas fractions released by stepwise heating of the Martian meteorite ALH 84001 (Bogard and Garrison 1999), which has been suggested to host microfossils. By irradiation in a nuclear reactor, fast neutrons change the ^{39}K of the sample (which is in constant proportion with ^{40}K) into ^{39}Ar . The $^{39}\text{Ar}/^{40}\text{Ar}$ is a substitute for the $^{40}\text{K}/^{40}\text{Ar}$ ratio. The ages are plotted as

a function of the progressive release of ^{39}Ar . A plateau age (here 4.3 Ga) indicates that large fractions of the sample kept the memory of the same chronological event. Anomalous ages at low temperatures (small fractions of ^{39}Ar released) indicate partial resetting by weathering or reheating. Anomalous ages at high temperatures indicate trapping of anomalous Ar components

This is the standard “isochron” equation. Figure 3 shows how an isochron based on the system ^{176}Lu – ^{176}Hf :

$$\left(\frac{^{176}\text{Hf}}{^{177}\text{Hf}}\right)_t = \left(\frac{^{176}\text{Hf}}{^{177}\text{Hf}}\right)_0 + \left(\frac{^{176}\text{Lu}}{^{177}\text{Hf}}\right)_t (e^{\lambda_{176}\text{Lu}t} - 1) \quad (10)$$

and a similar isochron based on the system ^{147}Sm – ^{143}Nd date 2.1 Ga old Birimian basalts from West Africa (Blichert-Toft et al. 1999). D/D' represents the ratio of the radiogenic nuclide to its stable isotope (e.g., $^{176}\text{Hf}/^{177}\text{Hf}$), and P/D' is the “parent/daughter” ratio, in most cases proportional to an elemental ratio (e.g., $^{176}\text{Lu}/^{177}\text{Hf}$). If two samples 1 and 2 formed at the same time from an isotopically homogeneous medium (ocean, magma), they share the same $(D/D')_0$, and, taking

the ^{176}Lu – ^{176}Hf system as an example, the time is obtained from

$$t = \frac{1}{\lambda_{176}\text{Lu}} \ln \left[1 + \frac{\left(\frac{^{176}\text{Hf}}{^{177}\text{Hf}}\right)_2 - \left(\frac{^{176}\text{Hf}}{^{177}\text{Hf}}\right)_1}{\left(\frac{^{176}\text{Lu}}{^{177}\text{Hf}}\right)_2 - \left(\frac{^{176}\text{Lu}}{^{177}\text{Hf}}\right)_1} \right] \quad (11)$$

This age dates the time at which the two samples last shared the same $^{176}\text{Hf}/^{177}\text{Hf}$ ratio, and their parent/daughter ratios (here Lu/Hf) were fractionated. This method is commonly used for parent/daughter systems with a long half-life, typically ^{147}Sm – ^{143}Nd , ^{176}Lu – ^{176}Hf , and ^{187}Re – ^{187}Os . The ^{87}Rb – ^{87}Sr technique is broadly used to date medium-temperature metamorphic events, ^{147}Sm – ^{143}Nd for the emplacement of ancient basalts and komatiites, ^{176}Lu – ^{176}Hf in

Geochronology, Fig. 3 Two examples of isochrons, using the ^{176}Lu - ^{176}Hf (top) and ^{147}Sm - ^{143}Nd (bottom) systems on the same early Proterozoic basalts from West

Africa (Blichert-Toft et al. 1999). Slopes of these isochrons give the age at which these volcanic rocks were extracted from the mantle

garnets for high-temperature ($>600^\circ\text{C}$) metamorphic events, and ^{187}Re - ^{187}Os for the deposition of reduced sediments (black shales) and some ores.

A particular application is the Pb-Pb method, which combines the two chronometers ^{206}Pb - ^{238}U and ^{207}Pb - ^{235}U . Equation (6) for the former system slightly modified as

$$\left(\frac{^{207}\text{Pb}}{^{204}\text{Pb}}\right)_t - \left(\frac{^{207}\text{Pb}}{^{204}\text{Pb}}\right)_0 = \left(\frac{^{235}\text{U}}{^{204}\text{Pb}}\right)_t (e^{\lambda_{235}t} - 1) \quad (12)$$

is divided by the equation for the latter

$$\left(\frac{^{206}\text{Pb}}{^{204}\text{Pb}}\right)_t - \left(\frac{^{206}\text{Pb}}{^{204}\text{Pb}}\right)_0 = \left(\frac{^{238}\text{U}}{^{204}\text{Pb}}\right)_t (e^{\lambda_{238}t} - 1) \quad (13)$$

to give

$$\begin{aligned} \frac{\left(\frac{^{207}\text{Pb}}{^{204}\text{Pb}}\right)_t - \left(\frac{^{207}\text{Pb}}{^{204}\text{Pb}}\right)_0}{\left(\frac{^{206}\text{Pb}}{^{204}\text{Pb}}\right)_t - \left(\frac{^{206}\text{Pb}}{^{204}\text{Pb}}\right)_0} &= \frac{^{207}\text{Pb}^*}{^{206}\text{Pb}^*} \\ &= \frac{1}{137.88} \times \frac{e^{\lambda_{235}t} - 1}{e^{\lambda_{238}t} - 1} \end{aligned} \quad (14)$$

where we used the observation that, today, the $^{238}\text{U}/^{235}\text{U}$ ratio is constant and equal to 137.88.

The asterisk stands for radiogenic Pb. Here the two parent nuclides on the one hand and the two daughter nuclides on the other hand are isotopes of the same element, which dispenses the analyst from measuring the U and Pb contents. In a plot of $^{207}\text{Pb}/^{204}\text{Pb}$ versus $^{206}\text{Pb}/^{204}\text{Pb}$, samples formed at the same time from the same reservoir define a straight line (another isochron) (Fig. 4), and the formation age can be retrieved from the slope. Historically, this is how Clair C. Patterson determined the age of the solar system. For statistical reasons, it is today common practice to use a $^{207}\text{Pb}/^{206}\text{Pb}$ versus $^{204}\text{Pb}/^{206}\text{Pb}$ isochron plot instead, in which the intercept, and not the slope, of the isochron gives the $^{207}\text{Pb}^*/^{206}\text{Pb}^*$ ratio and therefore the age. Figure 4 shows an isochron representing the Pb-Pb data on chondrules, little spherical blebs of molten material, and calcium-aluminum-rich refractory inclusions (► CAIs) from the ► carbonaceous chondrite Allende (Connelly et al. 2008), which represents one of the finest attempts to date an early sample of planetary material.

Extinct Radioactivities

A third class of chronometers relevant to astrobiology is that of extinct radioactivities. These have a short half-life (and therefore a large λ). For large values of λt , P becomes negligible, and therefore the closed-system condition reads

$$D_{\text{today}} = P_t + D_t \quad (15)$$

Let us write this equation for a sample (spl) and divide it by the abundance $(D')_t = (D')_{\text{today}}$ of a stable isotope of D

$$\left(\frac{D}{D'}\right)_{\text{today}}^{\text{spl}} = \left(\frac{D}{D'}\right)_t^{\text{Earth}} + \left(\frac{P}{P'}\right)_t^{\text{Earth}} \left(\frac{P'}{D'}\right)_{\text{today}}^{\text{spl}} \quad (16)$$

in which we introduce P' , a stable isotope of the parent nuclide ($P'_t = P'_{\text{today}}$). Using Eq. (9), this equation is equivalent to

Geochronology, Fig. 4 A Pb-Pb “inverse” isochron of refractory calcium-aluminum-rich inclusions and chondrules (small blebs of molten silicates) (Connelly et al. 2008), which accounts for most of the material in the

carbonaceous chondrite Allende. The age given by the intercept (no stable ^{204}Pb , so Pb is purely radiogenic) gives 4567 Ma, one of the oldest estimates of the age of the solar system

$$\left(\frac{D}{D'}\right)_{\text{today}}^{\text{spl}} = \left(\frac{D}{D'}\right)_{\text{today}}^{\text{Earth}} + \left(\frac{P}{P'}\right)_t^{\text{Earth}} \times \left[\left(\frac{P'}{D'}\right)_{\text{today}}^{\text{spl}} - \left(\frac{P'}{D'}\right)_{\text{today}}^{\text{Earth}} \right] \quad (17)$$

For the example of the ^{182}Hf – ^{182}W chronometer ($T_{1/2} = 8.9$ Ma) (Fig. 5), this equation reads

$$\left(\frac{^{182}\text{W}}{^{183}\text{W}}\right)_{\text{today}}^{\text{spl}} = \left(\frac{^{182}\text{W}}{^{183}\text{W}}\right)_{\text{today}}^{\text{Earth}} + \left(\frac{^{182}\text{Hf}}{^{180}\text{Hf}}\right)_t^{\text{Earth}} \times \left[\left(\frac{^{180}\text{Hf}}{^{183}\text{W}}\right)_{\text{today}}^{\text{spl}} - \left(\frac{^{180}\text{Hf}}{^{183}\text{W}}\right)_{\text{today}}^{\text{Earth}} \right] \quad (18)$$

This is the equation of the extinct radioactivity isochron. The conventional isochron cannot be used when all the parent nuclides have decayed away. When $^{182}\text{W}/^{183}\text{W}$ is plotted against $^{180}\text{Hf}/^{183}\text{W}$ (note that the two nuclides of the latter ratio are both stable), samples formed at the same time in isotopic equilibrium within the

Earth (e.g., mantle and core) define a straight line. The slope of this isochron varies with time as

$$\frac{\left(\frac{^{182}\text{W}}{^{183}\text{W}}\right)_{\text{today}}^{\text{spl}} - \left(\frac{^{182}\text{W}}{^{183}\text{W}}\right)_{\text{today}}^{\text{Earth}}}{\left(\frac{^{180}\text{Hf}}{^{183}\text{W}}\right)_{\text{today}}^{\text{spl}} - \left(\frac{^{180}\text{Hf}}{^{183}\text{W}}\right)_{\text{today}}^{\text{Earth}}} = \left(\frac{^{182}\text{Hf}}{^{180}\text{Hf}}\right)_t^{\text{spl=Earth}} = \left(\frac{^{182}\text{Hf}}{^{180}\text{Hf}}\right)_0^{\text{Earth}} e^{-\lambda_{^{182}\text{Hf}} t} \quad (19)$$

Extracting time from this equation requires that $(^{182}\text{Hf}/^{180}\text{Hf})_0$ of the Earth is known. However, dividing this equation for the core ($^{182}\text{Hf} \approx 0$) by the same equation for the mantle gives the age mantle-core separation.

This method is employed for a number of “extinct” short-lived nuclides. The chronometers ^{26}Al – ^{26}Mg ($T_{1/2} = 700,000$ Ma), ^{60}Fe – ^{60}Ni ($T_{1/2} = 2.6$ Ma), ^{53}Mn – ^{53}Cr ($T_{1/2} = 3.7$ Ma), ^{182}Hf – ^{182}W ($T_{1/2} = 8.9$ Ma), and ^{129}I – ^{129}Xe ($T_{1/2} = 15.7$ Ma) provide essential chronological information on the accretion of planetary material

Geochronology, Fig. 5 Dating of core-mantle segregation by the ^{182}Hf – ^{182}W method (Yin et al. 2002). The difference in slope between the alignment of the points representing the chondrites and that representing the silicate Earth is a measure of the last fractionation of the Hf/W

ratio. Tungsten fractionates into the metal and Hf into the silicate. The point of intersection of the two lines represents the unfractionated solar nebula. The difference in slopes show that core-mantle separation in the Earth occurred some 30 Ma after the formation of the solar system

from the solar nebula, its thermal history, and metal-silicate (core-mantle) segregation, while the ^{146}Sm – ^{142}Nd ($T_{1/2} = 103$ Ma) system proved essential to demonstrate the existence of very early crust.

Closure Temperatures

What chronology dates is actually not discrete formation events. Upon cooling, minerals keep exchanging radiogenic isotopes with their surroundings: the chronometric system is open. In most cases, what a chronometer records is therefore the time at which diffusion stopped (Fig. 6). Diffusion of a particular ion is a thermally activated molecular process of exchange between adjacent minerals or between a phase and the interstitial medium and is characterized by the energy of activation E and the so-called pre-exponential term D_0 . If cooling is fast, the closure temperature T_c (in K) is given by Dodson's (1973) implicit equation:

$$T_c = \frac{E}{R \ln [AD_0RT_c^2/Ea^2(-dT/dt)]} \quad (20)$$

in which R is the gas constant, a the grain size, $-dT/dt$ the cooling rate, and A a constant equal to 55. If cooling is fast, the radio-metric system dates the time at which temperature in the rock dropped below a particular value. The transition is usually fast (a few tens of degrees). Typical closure temperatures vary from 1000 °C for U-Pb in zircons to 800 °C for Pb-Pb in pyroxene and Lu-Hf in garnet and to 300 °C for K-Ar in feldspar and Re-Os in sulfides. If cooling is very slow, the system remains ajar for a long time, the demise of diffusion is sluggish, and the significance of the date is blurred.

Diffusion loss is one of the major issues of geochronology. Rocks from the sublithospheric mantle evolve for long times above the closure temperature and therefore cannot be dated by isotopic chronometers. The closure temperature varies as $2 \ln a$, so chronometers in smaller systems, first and foremost isolated crystals, close at a lower temperature than in the larger ones and may be easily reset by mild thermal events. Isochrons of large whole-rock samples are often used to mitigate this problem.

Geochronology,

Fig. 6 Cooling age and closure temperature of a chronometric system with decay constant λ . The cooling time and the corresponding cooling age t_c are defined by linearly extrapolating the ingrowth of radiogenic nuclides at zero, while the closure temperature T_c is the temperature of the mineral at this time. The system is open and loses the daughter isotope for $T > T_c$ and is closed for $T < T_c$. The slope of the daughter isotope evolution curve is the activity λP

Basic Methodology

Choosing a particular chronological system to use for a given problem depends on the duration of the age or age difference to be assessed. Enough decay must have happened that it measurably affects the abundance of the daughter isotope. In practice, a chronometer gives no useful information if this interval exceeds five to eight half-lives.

The elements for which the isotope composition is sought are isolated in a variety of ways. Gases are extracted by heating and purified in high vacuum enclosures. Solid samples are normally digested with strong acids (HF, HNO₃, HCl) in pressurized vessels and the metals usually separated by ion chromatography. Isotope ratios are measured on mass spectrometers, which combine a source of ions, electrostatic acceleration, a magnetic filter, and a set of detectors. These instruments differ by the nature of their ion sources. Gas sources use the bombardment of an electron beam to ionize atomic gases and are used for O, C, He, Ar, Xe, etc. Thermal ionization mass spectrometers (TIMS) produce ions by evaporative ionization at the surface of a hot filament and are used for Sr, Nd, Pb, and Os. Inductively coupled plasma mass spectrometers (ICP-MS) (Fig. 7) use Ar ions produced in a coil submitted to rapidly

fluctuating currents to ionize the other elements: this relatively new technique accounts for most measurements for Hf, W, Mg, and Fe. Sputtering of the sample by a $\sim 30\ \mu\text{m}$ primary ion beam (SIMS or ion probe) is the method of choice for the in situ measurement of U-Pb ages in zircons (Fig. 8).

The precision of measurements is first and foremost limited by counting statistics: a mass spectrometer can be seen as a device counting ions arriving on a detector. The measurement can therefore be seen as another Poisson process, which for n “events” must be associated with a standard deviation of $\sqrt{n}$ and a relative error of $1/\sqrt{n}$. Let us assume that we use an ion probe with a $30\ \mu\text{m}$ beam size to measure the abundance of ^{207}Pb in a zircon crystal with density of $4.65\ \text{g cm}^{-3}$ and which contains 100 ppm Pb. We also assume that the beam excites a hemispherical volume below the spot and a 1% ion yield. We must therefore divide the weight of sputtered material by the molecular weight of Pb and multiply by the isotopic abundance of ^{207}Pb and finally multiply by the Avogadro number to obtain $\sim 0.01 \times (2/3 \times 3.14) \times (15 \times 10^{-4})^3 \times 4.65 \times 100 \times 10^{-6} / 207.2 \times 0.22 \times 6.0 \times 10^{24} = 2.1 \times 10^8$ counts (approximate numbers suffice), i.e., an excellent precision of 0.007%. Reducing the

Geochronology,

Fig. 7 The Nu 1700 large radius MC-ICP-MS (multiple-collector inductively coupled plasma mass spectrometer) of Ecole Normale Supérieure in Lyon, France. The essential parts of the mass spectrometer are shown. This instrument can measure the isotope composition of most ions on quantities as small as 10 ng (one billionth of a gram) with a precision of 0.005% or better

Geochronology,

Fig. 8 The Cameca 1280 ion probe (secondary ion mass spectrometer) of the Centre de Recherches Pétrographiques et Géochimiques de Nancy, France

G

beam size to 1 μm would deteriorate the precision to 1% and make the measurement essentially worthless. The quest for ages on smaller and smaller objects is intrinsically limited by the desired precision.

A second stringent limitation is contamination, which for many elements such as Pb forces the analyst to work in ultra-clean environments with filtered air and distilled reagents. Not all contamination and common Pb can be removed and hence constitutes a significant source of uncertainty on ages. A third problem affects the chronometers based on beta decay: the kinetic energy of some emerging electrons is so small that they go undetected, and the corresponding decay constant cannot be accurately determined. This is a limitation for the ^{87}Rb – ^{87}Sr , ^{176}Lu – ^{176}Hf , and ^{187}Re – ^{187}Os techniques, which can be mitigated to some extent by a cross-calibration with U–Pb ages.

Finally, a general limitation arises when data expected to form an alignment actually scatter beyond analytical errors. This can be due to (1) a lack of isotopic homogeneity at $t = 0$; (2) the failure of the closed-system assumption because of weathering or thermal resetting; and (3) a long duration of the event to be dated, for example, in case of slow cooling. The literature on least-

square regression with correlated or noncorrelated errors is abundant, but a standard reference is that of York (1969). Among all the codes used to evaluate alignments, the most broadly used software is ISOPLOT created by Ludwig (2003).

Geoethics

Jesús Martínez-Frías

Instituto de Geociencias, IGEO (CSIC-UCM), Madrid, Spain

Definition

Geoethics (from Greek γῆ/γῆ “Earth” and -ἠθικός/ἠθικός “ethics”) is an interdisciplinary field between Geosciences and Ethics which involves Earth and Planetary Sciences as well as applied ethics. It deals with the way of human thinking and acting in relation to the significance of the Earth as a system and as a model. Geoeducational, scientific, technological, methodological, and social-cultural aspects are included (e.g., sustainability, development, geodiversity and geoheritage, prudent consumption of mineral resources, appropriate measures for predictability and mitigation of natural hazards, geoscience communication, museology). In addition, the necessity of considering appropriate protocols, scientific integrity issues,

and a code of good practice – regarding the study of the abiotic world – is covered by this discipline. Studies on planetary geology (sensu lato) and *astrobiology* also require a geoethical approach (Martínez-Frías 2008; IAGETH 2011).

History

The term Geoethics was born in 1991 in Příbram (Czech Republic) and Dr. Vaclav Nemec is considered the father of this discipline (Nemec 1992). Meetings, symposia, workshops and specific sessions, and various initiatives on Geoethics have been organized in various countries (Czech Republic, China, Germany, Japan, Mozambique, Paraguay, Poland, Spain, among others) and more regularly in Russia and Italy. The international institutionalization of geoethics was established in 2004, by forming a working group with the backing of the Association of Geoscientists for International Development (AGID). In 2008, Geoethics was, for the first time, incorporated in the official program of the 33rd International Geological Congress under the auspices of AGID, in Oslo. In 2011, a new international, peer review, open access journal *Geosciences* was introduced, which, for the first time, comprised Geoethics as one of its subject areas (Martínez-Frías 2011), and the First International Declaration on Geoethics was launched in Příbram, under the AGID umbrella (AGID_Geoethics 2011). 2012 was a key year for geoethics: (a) two international organizations about this discipline were affiliated to the IUGS; (b) geoethics was included and mentioned in the United Nations Conference on Sustainable Development (UNCSD) or Earth Summit Rio + 20 (Riccardi 2012), which was held in Rio de Janeiro (Brazil), and (c) the first monograph about geoethics (Nikitina 2012) was published in Russia.

Geoethics is a discipline which covers all the key subjects, essential knowledge, deontological behavior, and methodological and practical issues linking Ethics and Geosciences. A significant development in space science and technology has been achieved in the past century. Geoscientists have new skills and tasks linking different

disciplines, applying different methodological procedures and technologies, and facing new scientific, social, and cultural challenges, from micro- to macroscale studies, and from land, atmosphere, and oceans to planetary exploration (including their responsibility and implications in the search for life beyond Earth – given the significant role of planetary geology in *astrobiology*) (Martínez-Frías et al. 2011). Hence, Geoethics refers basically to all ethical subjects related to the abiotic world on Earth and also in other planets, moons, and planetary bodies. In this sense, it has been proposed that the incorporation of the geoethical and geodiversity issues in planetary geology and astrobiology studies would enrich their methodological and conceptual character (Martínez-Frías 2008; Martínez-Frías et al. 2009a, b). The International Association for Geoethics (IAGETH), which is affiliated to the IUGS and IUGG, is the only organization, linking ethics and geosciences, which included planetary geology and *astrobiology* in its foundational definition and goals (IAGETH 2011), and it has supported several symposia and initiatives about these subjects (ICOG 2018). The incorporation, through geoethics, of new questions associated to the *abiotic world* is, besides widening the classical concept of Planetary Protection (Rummel et al. 2002), giving an additional dimension to the geological research of the solar system. *Astrobiology* is part of the “Geoethical dilemmas through the prism of new challenges of time,” which were included in the IAGETH Plan of Activities (IAGETH 2013) and, in this framework, several initiatives linking geoethics and astroethics were developed (e.g., an international working group on astroethics was founded in 2016 in close collaboration with the TD 1308 COST Action ORIGINS) (Martínez-Frías 2016; Martínez-Frías and Gargaud 2016). One of the main tasks of the WG (IAGETH 2017) is to analyze the potential societal and ethical implications related to *astrobiology*, taking into account the complexity of the connections between its main scientific issues and goals, and considering the synergies between both bioethical and geoethical approaches (from microbes to humans and from the Earth to space environments).

Geological Time Scale, History of

Pierre Savaton

Université de Caen Basse-Normandie, Caen, France

Keywords

Chronology · Radiometric dating · Stratigraphic scale

History

Geology is the first historical science. Concept of time is a key concept in geology. Even if some geological processes operate over time of a few seconds (e.g., earthquake waves), most of them operate over million to hundreds of millions of years. Thus, to tell the Earth's history, we need to build a geological time scale to place geological events and measure their length. This scale results from a combination of time and space relations between rock formations (relative age) and from the measure of spontaneous decay of radioactive nuclides contained in rocks (absolute age). The only record we have of past geological events is the rock preserved from erosion, alteration, and plate tectonics.

The geological time scale was first a chronological one, without date. Study of sedimentary rocks had allowed first "geologists" to establish the simple basis for the stratigraphic scale.

Danish naturalist Nicolas Steno (1638–1686) noted that gravels, sands, and clays were laid down in more or less horizontal layers, which he called strata. In 1669, in his *Prodromus (De solido intra solidum naturaliter content dissertations prodromus)*, he enunciated principles of stratigraphy: original horizontality, superposition, and lateral original continuity of layers. Using these

principles, it was possible to arrange layers in a chronological succession, and some attempts were tempted and offered local descriptions of the pile of stratas. Steno identified in these successions some angular unconformities, which represented breaks in the stratigraphical record, but without understanding their possible use in dating of geological events, even if he showed that "geology" revealed a history. By contrast, he recognized that fossils were the remains of once living organisms. In 1667, working in Tuscany, he noted that shark teeth bore a striking resemblance to some stony objects found embedded within rock formations, called "tongue stones."

English philosopher Robert Hooke (1635–1703) considered fossil's shells as medals or monuments of nature, as greatest and more lasting monuments and records of antiquity. He claimed that animals living today might not have been alive in the past and animals presented in the past were no longer present today. He interpreted the differences between past and actual faunas by imagining a kind of transformation of species in time. This idea was taken back later by Leibniz before being developed and theorized by Jean-Baptiste Lamarck. But it was too premature for the 1600s. Hooke used for the first time the word "chronology" and suggested a powerful tool to date geological layers. These medals (fossils) allowed establishing continuity between layers separated by great distance or layers of different lithology. They allowed replacing geographical isolated layers in a succession. Robert Hooke might be considered a precursor of the idea of index fossil, that is, fossils of organisms that lived in a short time span but widely distributed geographically. But the time-keeper aspect of fossil's records remained marginal for a long time.

German geologist and mineralogist Abraham G. Werner still had neglected them in his *Kurze Klassifikation und Beschreibung der verschiedenen Gebürsarten* (1783), a stratigraphical framework attempt that was widely adopted like scheme of the succession of geological times. Fossils were just used to characterize his *formations*, but no more. Faunal succession, as the lithologic succession, could be used directly to identify rocky formations. This approach was that

used by British geologist William Smith to build his *Geological Map of England and Wales and part of Scotland* (1815). His *Strata identified by organized fossils* (1816–1819) paved the way for the development of the biostratigraphy. George Cuvier's and Alexandre Brongniart's map and *Description géologique des environs de Paris* (1811) proposed to use fossils to distinguish marine from continental sediments and to explain succession of sedimentological events. They used them as indicators of paleoecological conditions rather than strict stratigraphical tools.

In a few decades in the early 1800s, the geologists who mapped the world established a time scale based on assemblages of fossils, far more complex than the earlier succession of rocks (primary, secondary, tertiary) of the 1700s based on a lithological time scale.

Time and history of the Earth was divided in time units chronologically distinguished both by their vertical spatial relationships and their fossils content. Fossils determined a major division between the early time of the Earth, without visible fossils and the Phanerozoic time (today the fourth *eon*) characterized by its fossil diversity. Phanerozoic was subdivided into eras, periods, and epochs. The development of a systematic palaeontology during the nineteenth century and studies of some of the less visible one revealed new fossil discontinuities in the time and justified new subdivisions. French naturalist Alcide d'Orbigny showed how microscopic fossils, especially Foraminifera, could be used to characterize Cenozoic stratas. Paleontologists who studied the Jurassic ammonites identified species with a very short time range and suggested to use them to define small biostratigraphic units (biozones).

The theory of the Evolution of Darwin (1859) wasn't necessary to think a biostratigraphic scale, but gave a new breath to the fossil's tool. The succession of changing fauna could be explained by successive destructions and creations, migrations, or evolution. In the continuity of Cuvier thinking, most of the first stratigraphers favored extinctions. Proposing that new species emerged as a result of modifications to earlier species was more powerful. But the theory of evolution obliged to reconsider the age of the

Earth, because progressive changes required longer time.

The Archbishop Ussher of Ireland wrote in 1664 that the Earth was created 4,004 years before Christ. He had not been alone to interpret the Bible word for word to determine the antiquity of the Earth. All these biblical ages were very short. George Buffon, who believed in a cyclical history of the Earth, clearly longer than that given in the biblical accounts, published in his *Epoques de la Nature* (1778) an empirical calculation of the age the Earth. Following the idea that the Earth might originally have been molten, he measured the cooling time of iron balls of different sizes, and other materials, and concluded through this model that Earth should have been 75,000 years old. This duration was to great enough for many of his contemporaries.

The uniformitarian's ideas spread by British geologist Charles Lyell suggested estimating the actual age of the Earth using sediment accumulation or denudation rate as indicators of time. John Phillips transformed the unit of geological time into an equivalent term of years and proposed in 1860 in *Life on the Earth* an age of Phanerozoic time between 38 and 96 million of years. It wasn't enough for explaining the evolution theories of Darwin but compatible with ages calculated by British physicist William Thomson (better known as Lord Kelvin) through his model of a cooling Earth. Most of the geologists of the 1800s believed that Earth of the first time had been molten. Solid today, still hot, it would lose heat by conduction, compatible with the increasing temperatures recorded in mines or boreholes. In 1862, using Fourier's laws of cooling, Thomson estimated the Earth's center temperature to about 3,800 °C and the age of the Earth to about 20–400 million years. In 1897, Thomson, now Lord Kelvin, ultimately settled on an estimate that the Earth was 20–40 million years old.

The discovery of radioactivity by Henri Becquerel in 1896 and the isolation of radium by Pierre and Marie Curie in 1898 changed the classic view of a cooling Earth and offered to geology the tool it needed to measure time. The work of Rutherford and Soddy about radioactive decay series and the discovery that lead was the end

product of the uranium decay chain by American chemist Bertram Boltwood in 1905 stated the fundamental basis of radiometric dating and allowed geologists to put absolute dates in their geological column. Using what he knew about radium-lead decay, Boltwood aged rocks from 250 million to 1.3 billion years old. Although his estimate of the Earth's age was inaccurate, his paper, published in 1907, made clear that sediments from the same layers had similar uranium-lead ratios and that generally samples from younger layers had a lower proportion of lead.

In 1911, British geologist Arthur Holmes determined an age of 1,640 million years for Archean rocks and published in 1913, in *The Age of the Earth*, the first stratigraphic time scale with radioactive ages for the boundaries of the main units. He estimated the beginning of the Phanerozoic time at about 600 million years before present (today this limit is fixed at 542 Ma). Arthur Holmes's time scale established in 1947 was very similar than these of today. Working on lead isotopes in iron and stone meteorites, American geochemist Clair Patterson established and published in 1956 an age of the Earth of $4,550 \pm 70$ million years.

With fossil's chronology of sedimentary rocks and radioactive age of crosscutting igneous rocks, geologists have built the geological time scale. Earth history could finally be told.

Geological Timescale

Felix M. Gradstein

University of Oslo, Oslo, Norway

Definition

The Geologic Time Scale is the framework for deciphering and understanding the long and complex history of the Earth. Understanding the physical, chemical, and biological processes since the Earth formed requires a detailed and accurate timescale. The timescale is the tool “par excellence” of the geological trade (Gradstein et al. 2004; Ogg et al. 2008).

History

British geologist Arthur Holmes (1890–1965) was the first to combine radiometric ages with geologic formations in order to create a geologic timescale. His book, *The Age of the Earth* (1913, 2nd edition 1937), written when he was only 22, had a major impact on those interested in ► [geochronology](#). For his pioneering scale, Holmes carefully plotted four radiometric dates, one in the Eocene and three in the Paleozoic from radiogenic helium and lead in uranium minerals against estimates of the accumulated maximum thickness of Phanerozoic sediments. If we ignore sizable error margins, the base of Cambrian interpolates at 600 Ma, curiously close to modern estimates (541 ± 1.0 Ma). The new approach was a major improvement over a

previous “hour-glass” method that tried to estimate maximum thickness of strata per period to determine their relative duration but had no way of estimating rates of sedimentation independently.

Overview

Calibration to linear time of the succession of events recorded in the rocks on Earth has three components: (a) the international stratigraphic divisions and their correlation in the global rock record; (b) geochronology, the means of measuring linear time or elapsed durations from the rock record; and (c) the methods of effectively joining the two scales, the stratigraphic one and the linear one.

For clarity and precision in international communication, the rock record of Earth history is subdivided into a “chronostratigraphic” scale (Fig. 1) of standardized global stratigraphic units, such as “Devonian,” “Miocene,” “*Zigzag* ammonite zone,” or “polarity Chron C25r.” This chronostratigraphic calendar is not unlike a historical calendar in which civilization periods, such as the Minoan Period, Reign of Louis XIV, or American Civil War are used as building blocks, devoid of a linear scale. Archeological relics deposited during these intervals, such as the Palace of Minos on Crete, Versailles, or spent cannon balls at Gettysburg, comprise the associated physical chronostratigraphic record.

The chronostratigraphic scale is thus assembled from rock sequences stacked and segmented in relative units based on their unique fossil and physical content. This scale becomes meaningful and useful through correlation of the unique fossil and physical record to other sections of sedimentary or volcanic rocks in outcrops or wells across the globe.

The standard chronostratigraphic scheme, in downloadable graphic format and available from the International Commission of Stratigraphy (ICS) website (<http://www.stratigraphy.org/index.php/ics-chart-timescale>), is made up of successive stages in the rock record, for example, Cenomanian, Turonian, then Coniacian, etc.,

within the Cretaceous System. The chronostratigraphic scale is an agreed convention, whereas its calibration to linear time is a matter of discovery or estimation. The estimation comes from radiometric dating and astrochronology (orbital tuning of long sets of cycles) in the sedimentary rock record and is continually refined. Thus, the chronostratigraphic chart is updated, usually once a year.

In contrast to the Phanerozoic which has an agreed-upon chronostratigraphic scale with formal stage boundary stratotypes, Precambrian stratigraphy is formally classified chronometrically (see ► [Proterozoic Eon](#)).

Geomicrobiology

Ricardo Amils
Departamento de Biología Molecular,
Universidad Autónoma de Madrid, Madrid, Spain

Definition

Geomicrobiology examines the role of microbes in geological processes. Examples of such processes are the weathering of rocks, soil and sediment formation and transformation, the genesis and degradation of minerals, and the genesis and degradation of fossil fuels. Due to its transdisciplinary essence and the subject of study, geomicrobiology is of special astrobiological interest.

Geotherm

Daniele L. Pinti
Geotop, Research Centre for the Dynamics of the Earth System, Université du Québec à Montréal, Montréal, QC, Canada

Definition

Within a planet, the *geotherm* is the functional relationship between temperature T and depth

z below the surface. The geothermal gradient defines the increment of temperature per increment of depth, typically 30 °C per kilometer. Next to the surface, the geotherm is dominated by heat conduction. At steady-state, the curvature of the (T, z) curve reflects the distribution of heat sources, including radioactive heat production. The shallow geotherm is perturbed by porous fluid migration. At depth, mantle convection controls the geotherm, and variations in the properties of rocks (conductivity, thermal expansion, and compressibility) should be taken into account.

Geothermal Flux

- [Heat Flow, Planetary](#)

Geothermal Gradient

Nicholas Arndt
ISTerre, University Grenoble Alpes, Grenoble, France

Definition

The *geothermal gradient* is the increase in temperature with increasing depth, beneath the Earth's surface. This gradient is due to the outward heat flow from the hot interior (around 46 terawatts at the Earth's surface). Old geophysical models suggested that Earth's internal heat derives from a combination of residual heat from

planetary ► [accretion](#) (20%) and heat produced through radioactive decay of U, Th, and K (80%). Geoneutrinos measurements suggest however that the heat flow from radioactive decay could be much less, around 50% of the total heat (e.g., Korenaga, 2011). The magnitude of the geothermal gradient depends on the rate of heat production at depth, the dynamics of the system, and the conductivity of rocks. The highest gradients, 40–80 K km⁻¹, are measured at oceanic spreading centers (► [mid-ocean ridges](#)) or at island arcs where magma is close to the surface. The lowest gradients occur at ► [subduction](#) zones where cold lithosphere descends into the mantle. The gradient in old stable ► [continental crust](#) is ~30 K km⁻¹ and is somewhat lower in ► [cratons](#). Upwelling parts of the mantle ascend nearly adiabatically (i.e., they lose little to no heat to the surroundings), and the gradient is very low, about 0.3 K km⁻¹.

Geothermobarometers

Jean-Emmanuel Martelat
LST UMR5570, Université Claude Bernard Lyon
1, Grenoble, France

Keywords

Geobarometer · Geothermometer ·
Metamorphic rocks · Metamorphism

Definition

Geothermobarometers refer to all types of reactions that are useful to estimate temperature and pressure recorded in a magmatic or a metamorphic rock when it crystallizes or recrystallizes.

Overview

Minerals have different physical properties (e.g., volume, density, or entropy). When pressure increases, minerals such as quartz (density ≈ 2.66 g/cm³) may be metamorphosed into high-pressure polymorphs (e.g., for quartz: coesite, density ≈ 3.0 g/cm³). This kind of reaction is called polymorphic: the chemical composition remains SiO₂, but the atoms are rearranged in a more compact manner. On the other hand, as temperature increases, minerals such as kyanite (Al₂SiO₅) (standard entropy “S” at T = 298 $\approx$ 83 J/mol-K) may be metamorphosed into a high-temperature polymorph, sillimanite (Al₂SiO₅) (S at T = 298 K $\approx$ 93 J/mol-K), displaying a higher atomic disorder. Hence, a mineral or a mineral assemblage is sensitive to P-T conditions and is only stable within a given range of those conditions (see also ► [“Metamorphic Rock”](#) and ► [“Metamorphism”](#): metamorphic facies). Moreover, mineral compositions corresponding to a specific chemical equilibrium allow a quantitative estimate of P-T conditions: this method is called geothermobarometry. We use the term “geothermometer” for metamorphic reactions (or chemical equilibrium) that are highly sensitive to temperature and “geobarometer” for reactions that are sensitive to pressure.

Our ability to estimate or calculate the quantitative P-T conditions of a given rock depends on (1) the observation of the sample’s texture under the microscope, (2) the quality of the experimental calibration of the chemical reactions (stability field of mineral phases), (3) the accuracy of the thermodynamic properties of the minerals (database), and (4) the precision of chemical analyses on the minerals (e.g., with electron microprobes reaching a 1 μm^2 spot resolution).

On well-studied samples bearing relevant mineral assemblages, quantitative results can be obtained with an accuracy of ± 50 °C and ± 1 – 1.5 kbars. Several chemical reactions can help constrain the temperature. One of the most broadly used geothermometers is based on the diffusional exchange of Fe^{2+} and Mg^{2+} between garnet and biotite. Fe^{2+} and Mg^{2+} cations are easily exchangeable since they have similar electron valence and atomic radii. This exchange occurs without change in size of both the garnet and the biotite. The reaction is

where phlogopite and annite are the Mg- and Fe-pure end-member of biotite whereas pyrope and almandine are the Mg- and Fe-pure end-members of garnet, respectively. When temperature decreases, the Fe/Mg ratio decreases in biotite and increases in garnet. The most critical assumption behind temperature and pressure obtained by geothermobarometry is that equilibrium reactions were frozen during cooling. As diffusivity depends on temperature and on the distance between the exchange zones in the biotite and garnet in contact, one can obtain temperature gradients from the rim to the core of the given mineral pairs. Other equilibria can constrain temperature: e.g., polymorphic thermometer, solvus thermometer (e.g., feldspar exsolution), net transfer reaction thermometer (some minerals are consumed while others are produced), trace element thermometer, and stable isotope partitioning thermometer. Some other techniques, such as liquid–vapor homogenization points in fluid inclusions, provide quantitative thermometry results. The best way to obtain quantitatively the T and P recorded in rocks is to combine several internally consistent thermobarometers. Various freeware programs available on the Internet calculate numerous possible equilibria with respect to an internally consistent thermodynamic database for a large number of minerals (e.g.,

TWEEQ, Berman 1991; THERMOCALC, Powell et al. 1998).

Geysir

Definition

The term geyser derives from Icelandic *Geysir*, a geyser in southwestern Iceland. Its name means “spurt out”. Geyser is a type of hot spring that intermittently erupts hot water and steam, caused by the hydrothermal activity in volcanic areas. The formation of geysers is related to the uprising of pressurized water in rock conduits, at superheated conditions. Decrease of pressure close to the surface makes superheated water to rapidly change into steam (flashing) driving the hot water eruption. After the pressure decreases to a threshold value, the eruption stops and the system pressurizes again to initiate the following eruption.

Overview

On Earth, there are two types of geysers: fountain geysers and cone geysers. Fountain geysers erupt directly from a pool of water, while cone geysers erupt from a mound made of siliceous sinter (opal) called geyserite. Old Faithful, the most well-known geyser at Yellowstone National Park, USA, is a cone geyser. On Earth, geysers exist almost everywhere where there is a vigorous hydrothermal system, but a few places concentrate large amounts of them. The largest concentration of geysers in the world (300–500) is at Yellowstone National Park, followed by the Valley of Geysers in the Kamchatka Peninsula of Russia (200 geysers) and El Tatio, Chile (80 geysers), with many others in the Taupo Volcanic complex, New Zealand, and in Iceland.

On Earth, geysers have an astrobiology interest because, despite the harsh conditions of life around geyser’s mounds and pools, thermophile ($<60\text{ }^{\circ}\text{C}$) and hyperthermophile ($<110\text{ }^{\circ}\text{C}$) prokaryotes can develop. Thus, geysers are niches favorable to extremophile life and likely natural analogue of harsh conditions in the Hadean and Archean Earth.

There are other planetary bodies in the Solar System showing jet eruptions similar to geysers. Icy-cold volcanism (cryovolcanism) is also able to

reproduce geyser-like features called cryo-geysers. The Voyager 2 flyby of Neptune in 1989 showed geyser-like eruptions on its moon Triton. These eruptions are thought to be made of liquid nitrogen and dust and they were driven by solar heating. Similar solar heating-driven eruptions are believed to occur in the south pole region of Mars during spring thaw. Finally, pulsating bright plumes emanating from Enceladus’ south pole have been discovered by the Cassini flyby in 2005. These were interpreted as geysers drawing from a large body of liquid water. Tidal forces induced by Saturn’s gravity probably create sufficient friction to partially melt the ice crust of Enceladus and to create liquid water pools from which the geysers originate. Thus, cryo-geysers on icy moons could bring to their surface water and organics.

Giant Impact

Sean N. Raymond
Laboratoire d’Astrophysique de Bordeaux, CNRS,
Universite de Bordeaux, Bordeaux, France

Definition

During planetary formation, a giant impact is a collision between two planetary embryos with

masses of at least a lunar mass and often significantly larger. Planetary embryos are thought to grow by runaway and ► [oligarchic growth](#) from a swarm of small ► [planetesimals](#) primarily via embryo-planetesimal collisions. Once the local density of embryos and planetesimals is comparable, embryos can grow by embryo-embryo collisions. These so-called giant impacts are very energetic events whose consequences are not completely understood. In fact, most such impacts probably do not lead to perfect merging and probably generate significant amounts of collisional debris. The last giant impact on Earth is thought to have been a low-speed, off-center collision with a Mars-sized projectile, usually called Theia. The debris from this collision stayed in orbit around Earth and coalesced into the Moon.

Definition

The four giant planets in our solar system – ► [Jupiter](#), ► [Saturn](#), ► [Uranus](#), and ► [Neptune](#) –

are found in the outer solar system, at heliocentric distances ranging from 5 to 30 AU. Unlike the terrestrial planets – Mercury, Venus, the Earth, and Mars – located in the inner solar system, within 2 AU from the Sun, the giant planets are characterized by a large size, a large mass, and a low density. They all have a ring system and a large number of satellites. Since models show that the two largest giant planets have extensive gaseous envelopes, they are also referred to as “gas giants,” and there appear to be analogous objects in many extrasolar planetary systems. Tables 1 and 2 summarize the main orbital and physical properties of the giant planets.

History

Early Exploration

As naked-eye objects, Jupiter and Saturn have been known since antiquity. Their astronomical observation started in 1610 when ► [Galileo Galilei](#) used for the first time his new refractor to look at celestial bodies. Galileo discovered the four big satellites which orbit around Jupiter (later called Galilean satellites), the phases of Venus, the surface relief on the Moon, and the multitude of stars which populate the Milky Way. The discovery of the Galilean satellites had immense implications for the history of astronomy. It supported the heliocentric system proposed in 1543 by Nicolaus Copernicus and promoted by Johannes Kepler, but still strongly attacked by the theologians of Rome. Later, Isaac Newton elaborated the universal gravitation law, which provided the theoretical support of the heliocentric model and opened the era of celestial mechanics.

Galileo also noticed the changing aspect of Saturn as the orientation of the rings varied with respect to the Earth, but he could not provide an explanation. The answer was given by Christiaan Huygens in 1659, who also discovered ► [Titan](#), Saturn’s biggest satellite. At the end of the seventeenth century, large observatories were built and planetary observations took place on a regular basis. ► [Cassini](#) observed the zone and belt structure of Jupiter and noticed its Great Red Spot. He also discovered a gap inside Saturn’s rings, now

Neptune	17.14	3.88	1.64	16.11	28.80

called the Cassini Division, and he identified several icy satellites around Saturn. Cassini also used the precise timing of the Galilean satellites' mutual occultations to define a universal time and allow navigators to determine the longitude at sea. An even more spectacular result was the first measurement of the speed of light by Ole Rømer at Paris Observatory, based on the precise timing of the Galilean satellite occultations as a function of the Jupiter-Earth distance.

Thanks to improved techniques in the building of glasses and lenses, astronomical telescopes got more and more powerful. William Herschel, in particular, specialized in manufacturing a new generation of telescopes. In 1781, he discovered a new planet, which he called Uranus. The new planet was twice as far from the Sun as Saturn. At the same time, as a natural consequence of Newton's theory of universal gravitation, a new science, celestial mechanics, was developing rapidly. In 1821, the first precise calculations of the giant planets' orbits showed that the orbit of the new planet was perturbed by another more distant object. Two astronomers, John Couch Adams in England and Urbain Le Verrier in France, independently determined the position of the new object. John Adams was the first one to find the solution, but could not convince his director about the importance of his discovery. In 1846, Le Verrier sent the position of the new planet to a German astronomer, Johannes Galle, who immediately found it within 1° of its

predicted position. The planet was called Neptune; this discovery marked the triumph of the celestial mechanics.

Visual observations and drawings remained for long the only means for planetary cartography. Photographic plates were used from the beginning of the twentieth century until the apparition of the ► [CCD](#) digital cameras in the 1980s. In parallel, spectroscopic observations started to develop during the twentieth century. Spectroscopic observations are precious as they give information on the nature of the atmospheric constituents of the planets. In 1932, methane and ammonia were detected in Jupiter's atmosphere; in spite of their low relative abundance with respect to hydrogen, they were detectable because they are very active spectroscopic agents. Methane was detected also on the other giant planets. Molecular hydrogen, although by far the dominant atmospheric species on all giant planets, was not detected before the 1960s. Since the 1970s, several other minor species have been detected from ground-based observations, thanks to the development of infrared and millimeter spectroscopy.

The Space Exploration of the Giant Planets

The space exploration of the giant planets started in the 1970s with two programs, Pioneer and Voyager. Two spacecraft were first sent by NASA toward Jupiter and Saturn, Pioneer 10 and 11. Pioneer 10 was launched in 1972 and flew by Jupiter at the end of 1973; Pioneer 11 was

launched in 1973, flew by Jupiter in 1974, and took advantage of Jupiter's gravitational assistance to encounter Saturn in 1979. The Pioneer spacecraft were equipped, in particular, with a camera, ultraviolet and infrared photometers, a magnetometer, a plasma analyzer, and particle detectors. The Pioneer mission provided us with the first spectacular images of Jupiter's atmospheric structures and Saturn's rings, and they explored for the first time the planets' magnetospheres.

The first discoveries by the Voyager mission appeared soon after the success of the Pioneer spacecraft. Two identical spacecraft, Voyager 1 and 2, were launched by NASA in 1977. Flybys of Jupiter took place in 1979, and those of Saturn occurred in 1980 and 1981, respectively. Voyager 1 approached Titan for a close encounter of Saturn's satellite, while Voyager 2 used Saturn's gravitational assistance to encounter the other giant planets. Voyager 2 flew by Uranus in 1986 and by Neptune in 1989. The Voyager mission has been a spectacular success. In particular, Voyager 1 discovered the complexity of Jupiter's dynamical atmospheric structure, the active volcanism of the inner Galilean satellite Io, the possible water ocean below the surface of ► [Europa](#), the multiple structures of Saturn's rings, the magnetosphere of Saturn, and the nature of Titan's atmosphere. Voyager 2 discovered the magnetospheres of Uranus and Neptune, the unexpected tectonic activity of

Uranus' satellite ► [Miranda](#), the fascinating blue color of Neptune's atmosphere, and the active ► [cryovolcanism](#) at Triton's surface. The Voyager mission marked a major step in our understanding of the giant planets (Fig. 1).

After the flybys, a more in-depth exploration of the giant planets required the launch of additional orbiters and probes. In 1989, the Galileo mission was launched by NASA; it included an orbiter for successive flybys of the planet and the Galilean satellites and a probe for in situ measurements of the Jovian atmosphere. In spite of a technical problem which disabled the large antenna and imposed a very low telemetry rate, the Galileo mission was also a great success. On December 7, 1995, the Galileo probe entered the Jovian atmosphere and transmitted data down to a pressure level of 22 bars. The Galileo orbiter monitored the planet and the Galilean satellites until 2003. Unexpectedly, Galileo's magnetometer discovered, in particular, an intrinsic magnetic field on Ganymede.

After Jupiter, Saturn and its system also deserved an in-depth exploration. In 1997, the ambitious ► [Cassini](#) mission, jointly developed by NASA and ESA, was launched. The orbiter, led by NASA, was designed for an in-depth monitoring of Saturn, its rings, and satellites through multiple flybys. It approached Saturn's system in 2004. On January 14, 2005, the ► [Huygens](#) probe, led by ESA, successfully landed on Titan's

Giant Planets, Fig. 1 The Great *Red Spot* of Jupiter as revealed by the Voyager 1 spacecraft in 1979. (© NASA)

surface and sent to the world the first images of this new world. Among other spectacular results, the Cassini orbiter discovered lakes of hydrocarbons at the surface of Titan, cryovolcanism on Enceladus, and a very complex meteorology in the atmosphere of Saturn. The exploration continued until 2017, with two successive extensions. The next step in the space exploration of the giant planets is the Juno mission, launched by NASA in 2012, which encountered Jupiter in 2016 and is presently exploring its interior for a better understanding of its formation processes. Later, the JUICE (Jupiter and Icy moons Explorer) mission, selected by ESA for a launch in 2022, will approach the Jovian system in 2030. After a series of flybys, the spacecraft will be put in orbit around Ganymede for an exploration of possible habitability conditions in the icy satellites (Fig. 2). In parallel, the NASA probe Europa Clipper is expected to explore the Europa satellite through a series of successive flybys, also around 2030.

In addition to in situ exploration by dedicated planetary spacecraft, one should not forget the role of Earth-orbiting observatories. Both the International Ultraviolet Explorer (IUE), launched in 1978, and the Hubble Space Telescope (HST), launched in 1989, obtained UV spectra of the giant planets and Titan. The HST, in addition, gave excellent quality images of the

Giant Planets, Fig. 2 Saturn's rings, as seen by the Cassini spacecraft. (© NASA)

giant planets and the outer satellites, allowing long-term monitoring of the disk morphologies. The ► [Infrared Space Observatory](#), launched by ESA in 1995, sent infrared spectra which led, in particular, to the detection of an external oxygen source on all giant planets and Titan. ISO was followed by Spitzer, launched by NASA in 2003, and more recently by Herschel, launched by ESA in 2009, which has pursued the far-infrared and submillimeter exploration of the outer solar system.

Overview

The Formation of the Giant Planets

The striking differences between the main properties of the giant planets, as described above (Tables 1 and 2), and the terrestrial ones suggest a different formation scenario for the two types of planets. Indeed, there is presently a general agreement within the scientific community about a formation model of the solar system that does account for these specific properties.

It is now generally accepted that the solar system formed from a rotating fragment of an interstellar cloud, which collapsed into a disk perpendicular to its rotation axis. This model, called “model of the primordial nebula,” was first proposed in the eighteenth century by Immanuel Kant and later by Pierre-Simon de Laplace. Their justification for such a model was the simple observation of planetary orbits: they all rotate around the Sun on nearly coplanar and concentric orbits, in the same direction (direct, i.e., counterclockwise as seen from the north ecliptic pole), which is also the direction of the Sun's rotation. The baselines of this model are still valid today; later observations are totally consistent with this scenario. First, the chemical analysis of extraterrestrial samples (lunar samples and meteorites) has shown that all solar system bodies formed some 4.56 billion years ago, contemporaneously with the Sun itself. Second, observations of young nearby stars have revealed that the formation of a protoplanetary disk, following the collapse of an interstellar rotating cloud, is a common scenario of stellar formation. In addition,

hundreds of extrasolar planets have been discovered around nearby stars, either in these protoplanetary disks or after the dissipation of these disks.

The main lines of the solar system formation scenario can thus be summarized as follows. The protosolar disk, after the collapse of the protosolar cloud, is mostly composed of gas (hydrogen and, to a lesser extent, helium) with a small fraction of dust (metals, silicates). At the center of the disk, matter accretes to form the young Sun. The temperature is high at the center and decreases outward. The protosolar disk (see ► [“Solar Nebula”](#)) is very turbulent such that solid particles are permanently subject to mutual collisions. Because all particles revolve around the center, their relative velocities are small and collisions are not always disruptive; some of them lead to the formation of small aggregates. Following a mechanism that is not presently fully understood (possibly helped by the turbulence), some of these aggregates reach the kilometer size; they are called planetesimals. Then the biggest fragments are able to capture the surrounding particles by collisions and then by gravity. Numerical dynamical simulations show that after a few million years, a small number of big objects (of the size of terrestrial planets and satellites) are formed.

Why do we find two classes of planets, the terrestrial and the giant ones? This separation is a result of the condensation sequence that takes place within the disk as a function of the heliocentric distance. Within the disk, the element abundances follow the universal cosmic rule: the lightest one (hydrogen) is the most abundant (75% per mass), followed by helium (23%), and the 2% left is made of all heavier elements. Within these 2%, the lightest (C, N, O) are relatively more abundant than the heavier ones (Si, Mg, metals).

As planets were formed from solid material, the nature of the planet depends upon the nature of the solid material available to form the planetesimals. In the protosolar disk, the temperature decreases as the heliocentric distance increases. Two cases can be identified:

- Close to the Sun, within a few AU, the temperature (above 200 K) was such that the only

solid matter available was made of heavy atoms (metals, silicates). Because heavy elements are not abundant in the disk, the accretion process led to the formation of relatively small and dense planets: the terrestrial planets, also called the rocky planets.

- At larger heliocentric distance, the temperature (below ~ 180 K) became low enough for the small molecules (H_2O , CH_4 , NH_3 , H_2S , CO_2 , etc.) to condense. As these species were much more abundant than the heavier elements, they accreted into bigger cores, able to reach 10–15 terrestrial masses. At this point, models predict that their gravity field is sufficient for the surrounding nebula to collapse in a disk, in the equatorial plane of the planetary core. As the nebula is mostly made of hydrogen and helium, the planets formed after these collapses are very big, with a low density: they are the giant planets with their ring and satellite systems, formed within their equatorial disk.

Between the terrestrial and giant planets, the line of ice condensation is called the snow line. Water plays a special role for two reasons: first, formed from two abundant atoms, H and O, water is, among the ices, the most abundant small molecule; second, it is the first molecule to condense as the temperature decreases. Other ices (NH_3 , CO_2 , CH_4 , etc.) condense at greater heliocentric distances. Presently, water condenses at about 2 AU from the Sun, as shown by cometary activity. At the time of planets' formation, when the disk was warmer, the snow line was probably located at about 3–4 AU from the Sun.

The “core accretion model” of the giant planet's formation described above gives a natural explanation for the basic properties of the giant planets (size, mass, density, number of satellites). As will be discussed below, another observational fact supports this model: the elemental and isotopic abundances measured in the giant planets.

Gaseous Giants and Icy Giants

Table 2 shows the giant planets fall into two distinct subclasses. With masses of about 300 and 100 terrestrial masses, Jupiter and Saturn are mostly composed of protosolar gas: they are

called the gas giants. In contrast, Uranus and Neptune, with masses around 15 terrestrial masses, are mostly composed of their initial icy core; they are called the icy giants.

What can be the reason for such a difference? No definite answer can be given presently, but a plausible explanation can be proposed. Jupiter, formed just beyond the snow line, benefited from a maximum of icy material and a maximum of surrounding gas. To a lesser extent, Saturn's formation followed the same way. Jupiter and Saturn probably completed their formation within a few million years at most. In contrast, Uranus and Neptune, formed at larger heliocentric distances, needed a longer time to accrete their icy core. Possibly, they reached the critical mass of 10 terrestrial masses late enough for the protosolar disk to have dissipated, leaving little gaseous material for the planets to continue accretion. The lifetime of the protosolar disk, as inferred from the observation of protoplanetary disks around nearby stars, was probably not longer than ten million years, which may have been the time required by the icy giants to accrete their icy core.

Migration of the Giant Planets

Recent discoveries of extrasolar planets suggest that migration has been a common phenomenon in the planetary disks of nearby stars. Migration is usually generated by the interaction of the planet with the turbulent protoplanetary disk and leads the planet to move inward, from the outer stellar system to the close environment of its star. In the case of the solar system, dynamical simulations also suggest some migration might have taken place.

According to the “Nice Model” developed by Alessandro Morbidelli and his colleagues, after the dissipation of the protosolar disk, the giant planets were located on quasi-circular orbits between 5.5 and 17 AU, that is, significantly closer to the Sun than now. New numerical simulations suggest that this special configuration was the result of an earlier migration (the so-called Grand Tack) during which Jupiter came inward as close as Mars' orbit (thus interrupting the growth of Mars, which would explain the low

mass of the planet) and then migrated outward under the influence of Saturn. Later, gravitational perturbations may have induced again a moderate motion of Jupiter toward the inner solar system, while the three other giant planets moved outward. During this motion, the Jupiter-Saturn system crossed the 2:1 resonance (Saturn's revolution period being twice Jupiter's). According to dynamical simulation, this event generated a great perturbation in the inclinations and ellipticities of solar system small bodies. A clear signature would be the “► [Late Heavy Bombardment](#)” (LHB), traces of which are observed on the surfaces of all bare solar system objects, from Mercury and the Moon to the outer satellites. Crater rate counting on these objects shows that the event took place some 3.8 billion years ago, that is, about 800 million years after the planet's formation.

Comparison with other planetary systems raises a question: why was migration moderate in the solar system, while it seems to have been very efficient around nearby stars? Possibly, this was the result of the specific masses and locations of Jupiter and Saturn at the beginning of the scenario, but we have presently no firm answer to this question.

Atmospheric Composition of the Giant Planets

Because the atmospheres of the giant planets are dominated by hydrogen, atmospheric species are expected to be found in reduced form. This is the case for methane and hydrocarbons produced by its photodissociation. In addition, NH_3 , PH_3 , H_2O , GeH_4 , and AsH_3 are observed in Jupiter's and Saturn's tropospheres; these species are not observable on Uranus and Neptune because they condense below the observable atmospheric levels (at pressure levels of tens of bars). Methane also condenses on Uranus and Neptune at a level of 1 bar ($T = 80\text{ K}$), but especially on Neptune, its stratospheric content is sufficient to lead to the formation of hydrocarbons (in particular C_2H_2 and C_2H_6). The atmospheric composition of the giant planets is listed in Table 3.

Other unexpected stratospheric species have been discovered. In 1992, ground-based

Giant Planets, Table 3 Giant planets: mixing ratios of atmospheric constituents (fractional number density per unit volume relative to H₂)

^aDetected

millimeter observations of Neptune led to the detection of stratospheric CO and HCN, in abundances much larger than the predicted ones (those predicted values were actually observed in Jupiter’s and Saturn’s stratospheres). In 1997, the ISO satellite discovered the presence of H₂O on all giant planets and Titan (as well as CO₂ in Jupiter, Saturn and Neptune). CO was detected on Uranus from ground-based infrared spectroscopy. H₂O and CO were later also studied by the Herschel satellite. Because the thermal vertical profiles of the giant planets exhibit a cold trap at the level of the minimum temperature, at a pressure level of 0.1 bar (see below), the stratospheric oxygen species had to be of external origin. The source might be either local (rings and satellites) or interplanetary (comets or flux of

micrometeorites). Following Herschel observations, the water source is believed to be the Shoemaker-Levy collision of 1994 for Jupiter and the ► [Enceladus](#) torus in the case of Saturn.

From the abundances of tropospheric species, elemental and isotopic ratios have been determined. These parameters are important as they provide precious constraints for the formation models of the giant planets. Indeed, according to the nucleation formation model described above, heavy elements are expected to be enriched with respect to protosolar values; the larger the mass fraction of the icy core, the larger the enrichment. A simple model based on an initial icy core of 12 terrestrial masses predicts enrichment in heavy elements by a factor of 4 for Jupiter, 9 for Saturn, and about 30 for Uranus and Neptune, which is in

full agreement with the carbon enrichment measured from tropospheric methane in the four giant planets. It is also fully consistent with the enrichments measured in situ by the mass spectrometer of the Galileo probe for several elements (C, N, S, Ar, Kr, Xe). These results provide a clear validation of the nucleation formation model. Still, the Galileo measurements on Jupiter raise a problem: all elements seem to have been equally trapped in ices, but N and Ar cannot be trapped unless at very low temperature (<40 K). This suggests that the planetesimals which formed Jupiter were accreted at very low temperatures, much lower than expected at Jupiter's orbit. The origin of Jupiter's planetesimals is presently an open problem. It is hoped that the Juno mission will bring new answers to this question by measuring the O/H ratio in the planet's interior.

Another additional measurement supports the nucleation model. The D/H ratio measured in the outer solar system is diagnostic of its formation temperature. Indeed, **▶ deuterium** is enriched with respect to hydrogen in ices, due to ion-molecule and molecule-molecule reactions, as observed in the laboratory and in the **▶ interstellar medium**. The observed D/H ratio increases as the temperature decreases. The D/H ratio has been measured in the giant planets by the ISO satellite from HD infrared lines. These lines were later reanalyzed on Uranus and Neptune by the Herschel satellite. In the case of Jupiter and Saturn, D/H has been found to be in agreement with the protosolar D/H value, which is consistent with the fact that they are mostly made of protosolar gas. In contrast, following Herschel's results, D/H in Uranus and Neptune is enriched by a factor of about 2–2.5, which corroborates that these planets have an icy core.

The abundance of helium in the giant planets is also diagnostic of their formation and evolution processes. The He mass fraction Y was measured by the Voyager IRIS infrared spectrometers and, in the case of Jupiter, by the Galileo probe. Results were $Y = 0.234 \pm 0.05$ for Jupiter, 0.21 ± 0.03 for Saturn, 0.26 ± 0.05 for Uranus, and 0.32 ± 0.05 for Neptune. For Uranus and Neptune, the helium abundance is consistent with the protosolar abundance ($Y = 0.275 \pm 0.01$). In the

case of Saturn and Jupiter, the apparent depletion has been interpreted as a possible condensation of helium within the liquid hydrogen ocean in the planets' interiors (see below).

Thermal Structure, Cloud Structure, and Dynamics

The atmospheres of all giant planets are characterized by several layers: (1) a convective **▶ troposphere** where the temperature decreases as the altitude increases following an adiabatic lapse rate. The minimum temperature is reached at the tropopause, at a pressure level of about 100 mbar for all giant planets. The temperature at this level is 110 K for Jupiter, 90 K for Saturn, and 50 K for Uranus and Neptune. Above the tropopause, in the **▶ stratosphere**, the temperature increases again with altitude. In the lower stratosphere, the heating mechanism is probably the absorption of the solar flux by methane and hydrocarbon aerosols formed by methane photodissociation. At higher altitudes, other heating processes must be involved, such as gravity waves and energy deposition by high-energy particles.

The cloud structure of the giant planets can be estimated on the basis of thermochemical equilibrium models. In the case of Jupiter and Saturn, a cloud of ammonia is expected at a level of 0.5–1 bar, respectively ($T = 145$ K). An NH_4SH cloud is expected at $T = 210$ K, at pressure levels of 2 bars (Jupiter) and 4 bars (Saturn). At deeper levels, an H_2O cloud should occur at 270 K, at pressure levels of 5 bar (Jupiter) and 10 bars (Saturn). In the case of Uranus and Neptune, according to the models, CH_4 is expected to condense at a level of 1 bar ($T = 80$ K). Hydrocarbon hazes (especially C_2H_6) should be present in the stratosphere. An H_2S cloud could be present at about 3 bars ($T = 120$ K). In the lower troposphere, NH_4SH and H_2O clouds could be present at temperatures of 240 K and 270 K, respectively, at pressure levels of several tens of bars.

How do the observations fit the models? The spectroscopic identification of condensates is much more ambiguous and difficult than the detection of gaseous species. Still, imaging spectroscopy at different wavelengths provides a 3D imaging of planetary disks. Typically, ultraviolet

radiation probes the stratosphere, while the visible spectrum probes the upper troposphere; the 5-micron region, known as an “atmospheric window,” probes the troposphere down to a pressure of a few bars. In the case of Jupiter, the observations performed by the Juno probe in the radio range has shown that the vertical distribution of NH_3 , at a pressure level of 10 bars or more, is by far more complex and inhomogeneous than previously thought. It is constant with altitude only near the equatorial region, where the N/H ratio is close to three times the solar value, as previously measured (see above). At higher latitudes, the N/H ratio becomes homogeneous only for pressures higher than 20 bars. This complexity makes it difficult to infer the O/H ratio in the deep troposphere of Jupiter, because NH_3 and H_2O are both strong absorbers in the radio range.

Images of Jupiter and Saturn in the visible range show the typical zone-belt structure characteristic of a Hadley-type convective circulation in a fast rotating object. Zones are cloudy regions of ascending motion, while belts are dry, cloud-free regions of subsidence. The yellow color of Jupiter’s zones is consistent with the presence of an ammonia cloud. In Saturn, the more uniform yellow color of the disk implies a thicker ammonia cloud, consistent with the colder environment of the planet. On Jupiter, dark-blue regions in the belts have been attributed to water clouds. The Great Red Spot, known for over three centuries, is believed to be a giant anticyclonic structure. Its stability over such a long time is still a puzzle. Its red color has not been unambiguously interpreted. It could be due to the presence of sulfur or phosphorus compounds or to hydrocarbon polymers formed from the irradiation of ices by high-energy particles. In Saturn, a huge storm developed in the northern hemisphere in December 2010. This phenomenon has been observed for over a century with a period of approximately 28 years near the northern summer solstice. It is attributed to a massive atmospheric upwelling generated by a seasonal insolation increase.

The Galileo and Cassini observations have shown that, on both Jupiter and Saturn, the meteorology is by far more complex than described by a simple Hadley-type convective model. In the

case of Jupiter, the Galileo probe entered a region especially dry and free of clouds. In particular, the cloud structure described above was not found, and the measured water abundance was much lower than expected. This measurement was not considered as representative of the O/H value in the deep troposphere of the planet; determining O/H in the deep interior of Jupiter, using radio measurements, was thus among the objectives of the Juno mission (see above). In the case of Saturn, near-infrared images revealed a huge cyclone at the South Pole and a complex hexagonal structure surrounding the North Pole.

In contrast with the other giant planets, the image of Uranus shows little contrast. The images taken by Voyager 2 in 1986 showed no latitudinal structure. At the time of the Voyager encounter, the rotation axis of Uranus was nearly aligned with the Sun-planet axis. Twenty years later, when Uranus came to equinox, HST images revealed more activity, with cloud features at low latitude. In spite of some possible seasonal activity, Uranus is much less dynamically active than the three other giants. Is this difference connected to the special orientation of its rotation axis, very close to the ecliptic plane, or is it connected with the absence of an internal energy source (see below)? Or are the two effects connected with each other? This is an open question.

Finally, Neptune exhibits a strong dynamical activity, which is especially remarkable in view of its large distance from the Sun. Part of the explanation may come from its strong internal source of energy (see below). Methane in Neptune is supersaturated, which induces a strong methane photochemistry. The explanation might be the continuous insolation of the South Pole over the past 40 years, which could be responsible for the temperature increase measured at the tropopause; methane would be released in the stratosphere from the South Pole and spread over the planet. An active meteorology has been observed on Neptune over the past decades. In 1989, at the time of the Voyager encounter, a large feature (the Great Dark Spot) was observed. It was interpreted as a giant anticyclone, similar to Jupiter’s Great Red Spot. However, the feature had

disappeared a few years later when Neptune was imaged by the HST. Many other variable bright and dark spots, at different altitudes, have been monitored over the years. White spots are believed to be high-altitude cirrus of methane.

Internal Structure

Our knowledge of the giant planets' internal structure relies on theoretical models, constrained by a few physical parameters (mass, diameter, density, gravitational moments). According to these models, the internal structures of Jupiter and Saturn consist of three regions: a central core of ices and rocks, an ocean of metallic hydrogen, and an envelope of molecular hydrogen. At the center, the temperature is expected to be 23,000 K (Jupiter) and 12,000 K (Saturn); the pressure is estimated to be 50–100 Mbar (Jupiter) and about 50 Mbar (Saturn). However, in the case of Jupiter, the gravimetry measurements of the Juno probe have shown that there is no clear separation between the central core and the ocean of metallic hydrogen. This “diluted” nucleus might be the result of an early collision between the proto-Jupiter and a protoplanet of about 15 terrestrial masses.

In the case of Uranus and Neptune, the models predict also a core made of ices and rocks but no metallic hydrogen. The core would be surrounded by a mixture of ices and then by an envelope of molecular hydrogen. The central temperature would be about 7000 K and the central pressure about 6 Mbar.

Other information relative to planetary interiors come from the internal energy source that has been measured by Voyager from the total infrared emission of the planets. An internal energy source has been detected on Jupiter, Saturn, and Neptune; its ratio to the absorbed solar energy amounts to 1.67 for Jupiter, 1.78 for Saturn, and 2.6 for Neptune. In the case of Uranus, the ratio was less than 1.1; no internal energy was detected. A plausible source for the internal energy is radiative adiabatic cooling, following the early accretion phase of the planet's formation. If it is indeed the case, then the absence of internal energy on Uranus is puzzling. In the case of Jupiter and Saturn, according to models, an additional

internal source might come from the condensation of helium inside the metallic ocean of hydrogen. Helium droplets would sink toward the center, releasing energy upward and contributing to the depleted helium abundance in the outer layers; no helium condensation would be expected in the case of Uranus and Neptune, as the internal pressure is not sufficient for hydrogen to be in liquid form. This process would be consistent with the helium measurements in the giant planets (see above).

Magnetospheres

Like the Earth, all giant planets have a ► [magnetosphere](#). In the case of Jupiter, its magnetic activity was first identified in 1955 by the detection of strong radio emission. In addition to the thermal emission of the planet, nonthermal emission was found at centimeter and decimeter wavelengths. It was attributed to synchrotron emission of electrons trapped in the radiation belts of a newly detected magnetic field. The magnetospheres of Jupiter and Saturn were first explored by Pioneer 10 and 11 in 1974 and 1979, respectively, and the magnetospheres of Uranus and Neptune were discovered by Voyager 2 in 1986 and 1989, respectively. The magnetic fields of the giant planets, to first order, can be approximated by a dipole, probably generated by motions within the liquid central nucleus, also activated by the fast rotation of the planets.

The magnetospheres of the giant planets show a structure comparable with the terrestrial one and result from the interaction of the magnetic field with the ionized particles of the solar wind. In the case of Jupiter, the inner magnetosphere, within 20 planetary radii, has a dipole structure, inclined by 11° with respect to the rotation axis, with radiation belts similar to the Van Allen belts on Earth, where energetic particles are trapped. The magnetic field is perturbed by Jupiter's satellites Io, Europa, and Ganymede. Aurorae are observed in the ionosphere at high latitude, in the form of localized emissions in the ultraviolet and in the near-infrared range.

The Jovian magnetic field (14 G at the North Pole, 4 G at the equator) is ten times stronger than the terrestrial magnetic field. The other giant

planets have significantly weaker magnetic fields (0.2–0.3 G). Saturn’s magnetosphere shows no radiation belts, because of the presence of the rings. As Saturn’s magnetic axis is almost aligned with its rotation axis, its magnetosphere is much more regular than the Jovian one. Repeated observations of Saturn’s gravity field by the Cassini orbiter have revealed a variation of the internal rotation period of the planet, whose origin is still a matter of debate.

Both Uranus and Neptune show a very strange configuration, as their magnetic axes are tilted with respect to their rotation axis by a large angle (59° and 47°, respectively), with an offset of 0.3 and 0.5 planetary radii with respect to the planet’s center. This configuration induces complex magnetospheric structures, modulated by the rotation period of the planets. In the case of Uranus, the situation is even more complicated due to the position of the rotation axis, close to the ecliptic plane, which leads to strong seasonal effects.

Rings and Satellites

All giant planets have a ring system (see “► [Planetary Rings](#)”) and a large number of satellites; as mentioned above, this is a direct consequence of their formation scenario. The satellites were formed within the planet’s equatorial plane, after the collapse of the surrounding nebula on the initial icy core.

Rings are mostly found within the ► [Roche limit](#), at about two planetary radii from the planet’s center; in this region, tidal forces prevent the accretion of satellites, and dust particle revolve along circular orbits around the planet.

The giant planets show very different ring systems. Saturn’s rings have been observed over four centuries, while the three other ring systems were still undetected a few decades ago. The ring system of Jupiter, made of three tenuous components, was discovered by Voyager 1. They are made of micron-sized particles, probably ejected from the small nearby satellites (Thebe, Amalthea, Metis, and Adrastea). These particles have a very short lifetime, due to dynamical effects and erosion. Repeated observations of Saturn’s rings by the Cassini orbiter, in particular at the time of the “Grand Finale,” when the orbiter flew between

the rings and the planet in September 2017, have shown in detail the complexity of the interactions between the rings and the small nearby satellites.

The ring systems of Uranus and Neptune were both discovered by ground-based stellar ► [occultation](#) measurements. In 1977, nine very narrow rings were discovered around Uranus. The observation was made easier by the fact that the rotation axis of Uranus was almost facing the Earth at that time. The rings of Uranus were later imaged by Voyager 2 and then by the ► [HST](#). In 1984, another stellar occultation experiment was performed on Neptune. Absorption of the stellar flux was detected on one side of the planet only; it was interpreted as the presence of incomplete rings or “arcs.” In 1989, Voyager 2 confirmed this result but found that the rings were actually complete, but denser in some locations. The rings of Uranus and Neptune have a low albedo, possibly due to the presence of organic polymers resulting from the irradiation of organic ices by high-energy magnetospheric particles (Figs. 3 and 4).

The detailed structure of Saturn’s ring system has been revealed by Pioneer and Voyager and is being extensively explored by the ► [Cassini](#)

Giant Planets, Fig. 3 The rings of Neptune as observed by Voyager 2 in 1989. The denser regions correspond to the “arcs” previously identified from ground-based solar occultation observations in 1984. (© NASA)

Giant Planets, Fig. 4 The system of Uranus, observed in the near-IR range at the VLT (European Southern Observatory: ESO) in 2002. On this picture, satellites and rings are overexposed and the planet is dark because the near-IR filter (K-band) corresponds to a strong absorption band of methane. North is at the *bottom right* and east is at the *top right*. The satellites, from *left to right*, are Titania, Umbriel, Miranda, Ariel, and Oberon. (© ESO)

orbiter. Apart from the well-known A, B, and C main rings, a thin ring (D) has been found closer to the planet; other rings (A, F, G, E) have been found outside. The Cassini observations have shown that the E-ring is fed with the matter ejected by ► [Enceladus](#), which shows evidence for active ► [cryovolcanism](#).

Outer Satellites

All giant planets have many satellites, either regular (i.e., formed in the equatorial plane of the planet) or irregular (i.e., resulting from the capture of a distant asteroid or a ► [trans-Neptunian object](#)). All regular satellites are in synchronous rotation with their planet.

The outer satellites are all different, and each of them deserves a specific description. Here we will just mention some general trends. All outer satellites are made of ices. Water dominates in the case

of Jupiter (with the exception of Io, which has lost its water due to its active volcanism) and Saturn. The satellites of Uranus and Neptune, which have a lower albedo, probably contain other types of ices (N_2 , CH_4 , CO_2 , etc.) as is observed on ► [Triton](#).
